AN IMPORTANT CHANGE IN THE MODE OF ASYLUM TREATMENT.—The managers of the Morristown, N. J., Insane Asylum have decided to place the business management of the asylum in the charge of a warden, and to put the medical department under the care of "a competent alienist of advanced views—to be called the Medical Director," with four medical assistants. This change is a radical and significant one. Its success depends upon whether the warden and the medical director can work together harmoniously. The experiment will be watched with deep interest.

THE FAILURE OF THE "CAMPION" SCHEME for keeping up the price of drugs is what we expected; and it is now stated in the *American Druggist* that this plan has been practically abandoned by the manufacturers and wholesale dealers.

PROFESSOR MALLET, who was elected to the Chair of Chemistry in Jefferson College a short time ago, has resigned.

BERLIN.—The Society of Internal Medicine occupied its session, February 2d, with listening to the report by Dr. Leyden of a unique case of aneurism of the left ventricle of the heart. The Berlin Medical Society has taken up the matter of peptonizing milk. Dr. Ewald demonstrated the process to the members.

PARIS.—The Académie de Médecine continued at its session, February 10th, the discussion of the subject introduced by M. Le Fort, of the "Depopulation of France."

VIENNA.—At the Royal Society of Physicians, February 6th, a number of pathological specimens were shown and discussed. Dr. Schopf presented a specimen of congenital meningocele, Professor Kundrat a specimen of cyst of the lower eyelid in a case of congenital microphthalmia.

THE CONGRESS OF THE FRENCH SOCIETY OF OPHTHALMOLOGISTS held its first session in Paris, beginning January 26th, under the presidency of M. Juda, of Amsterdam.

PREVALENCE OF MEASLES.—During the past four months there have been 2,152 cases of measles in this city, with 402 deaths.

COMMENCEMENTS.—The Central College of Physicians and Surgeons of Indianapolis, Ind., graduated a class of ten on February 27th last.

* Dr. James E. Reeves, Secretary of the West Virginia State Board of Health, has been obliged to resign on account of ill-health. Dr. Reeves has been one of the most active and earnest health officers, and his retirement is a serious loss. Dr. L. D. Wilson has been appointed in his place.

The Missouri Board of Health Declared Unconstitutional.—The action of this Board in refusing registration to a person with a diploma from a college not in good standing, has been sustained by the courts (*Medical Herald*). But in the case of the Missouri State Board of Health *vs.* one Dr. J. C. McCoy, who had been arrested for not complying with the law regulating the practice of Medicine in this State, Judge Noonan, before whom the case was tried, ordered the discharge of the defendant on the ground that the Act creating the State Board of Health was unconstitutional, because the Board was made a Court with judicial powers; that the Legislature had no power to establish such a Court, and the said Court purports to try citizens and deprive them of property without trial by jury (*Periscope*).

Psychical Research.—A working section of the American Society for Psychical Research has been organized in this city, the membership being composed partly of laymen, but mainly of physicians who are more or less interested in neurological science. The work of the Society has been taken up with great enthusiasm in and about Boston.

The Toner Lectures are annual, semi-popular, medical lectures delivered at Washington, generally by Philadelphia physicians. The lecture last year, delivered by Dr. Charles K. Mills, was on the subject of the effects of mental over-work and strain in public and professional men.

Medical Matters in West Virginia.—A correspondent writes: "Of medical matters in West Virginia the only item of interest is the effort which is being made by some, who were shut out by the action of the Board of Health law, to induce our present Legislature to repeal it. It is not probable that it will be done."

The Hygiene and Homœopathy of Opera Singers.—Miss Kellogg writes in *The Critic:* "Different singers use different drinks for refreshing the throat, according as their experience has taught them. I have found beef-tea to be of great service. I have known some singers to use a gargle. Le Franc, the tenor, famous for his high C, used a salt-and-water gargle. The singers of a past generation depended a great deal upon sulphur, and so do those of to-day, only they take smaller doses. They take it homœopathically. Patti, I am told, puts a great deal of dependence upon *hepar-sulphur*. I use it, too, and so do other singers who are homœopathists; and most of them *are* homœopathists, for they find that prevention is the best treatment for their ailments. Nine hours a night—or never less than eight—are necessary for a singer to sleep, for her nervous force is heavily taxed."

Nitrate of Ammonia arrests oxidation in and about the nervous centres, and has been suggested against so-called nerve-storms. Searles' so-called oxygenated and aërated water contains about five times its volume of nitrous oxide gas, and has been used to some extent as an internal remedy.

Reviews and Notices.

Cocaine and Its Use in Ophthalmic and General Surgery. By H. Knapp, M.D., Professor of Ophthalmology in the Medical Department University of the City of New York. Pp. 87. New York and London: G. P. Putnam's Sons. 1885.

This work is a *resumé* of much that has been written on the subject of cocaine, together with the personal experience of the author, which is lucidly expressed. The original paper of Koller, read before the Medical Society of Vienna, and published in the *Wien. Med. Wochenschr.*, October 25 and November 1, 1884, is reproduced verbatim. This forms a most interesting prelude to the subsequent pages. No essentially new facts are adduced in the treatise, but its editor has done the professor an immense service by the painstaking labor involved in collaborating information from so many different quarters. The typographical appearance of the work deserves hearty commendation.

Building for the Children in the South. By Rev. A. D. Mayo. Pp. 16. Washington: Government Printing Office. 1884.

This modest pamphlet relates the author's impressions on the subject of education among the Southern people. It is particularly interesting in view of possible approaching national legislation in regard to the matter. Mr. Mayo has done yeoman's work in the cause, and speaks from personal observation. He lays particular stress on the need of good teachers, the establishment of libraries, and popular discussion of educational problems.

The Care of Infants: a Manual for Mothers and Nurses. By Sophia Jex Blake, M.D., Lecturer on Hygiene at the London Medical College for Women. Pp. 109. London: Macmillan & Co. 1884.

This little manual is full of common sense, and can be easily understood by any one of ordinary intelligence. Its watchwords are cleanliness, fresh air, and simple food. It dwells particularly on preventive medicine, and points out how infant mortality can be greatly lessened by following its good advice. Its author possesses the somewhat rare quality among writers, viz., of knowing when she has made her point and then stopping.

Manual of Obstetrics. By Edward L. Partridge, M.D., Professor of Obstetrics in the New York Post-Graduate Medical School, etc. Wood's Pocket Series. Pp. 295. New York: William Wood & Co. 1884.

This is a valuable addition to the handy Pocket Series. Its scope is, in the words of the preface, to aid the student "who desires to arrange and simplify his information, and at leisure moments to recall to his mind primary data necessary to his chain of knowledge." The text is clear and concise, and the illustrations remarkably well executed, considering the size of the work. To the busy practitioner it will not come amiss as an outline reference book, containing, as it does, allusions to all the necessary procedures of the obstetric art.

Diseases of the Urinary and Male Sexual Organs. By W. T. Belfield, M.D., author of "Relations of Micro-organisms to Disease" (Cartwright Lectures, 1883); Pathologist to the Cook County Hospital, Surgeon to the Genito-urinary Department, Central Dispensary, Chicago, Ill., etc. New York: Wm. Wood & Co. 1884.

The aim of this work, which constitutes the October volume of Wood's Library for 1884, is to set forth the necessity of and the means for arriving at a clear diagnosis of genito-urinary disease, before undertaking treatment in a given case. Accordingly Dr. Belfield has devoted especial attention to the means at our com-

mand for recognizing the actual pathological condition of the patient's genito-urinary system. He cares less for symptoms than for recognizable departures from normal structure.

He is emphatic in demonstrating that cystitis, gleet, albuminuria, spermatorrhœa, and allied conditions are symptomatic of some pathological departure from healthy structure. To ascertain the exact nature and extent of morbid alteration is a necessary pre-requisite of rational treatment. He very properly denounces the too-prevalent plan of routine-treatment of subjective symptoms. The book is clearly written, and there can be no mistaking the author's meaning. It will be a valuable study-book for the general practitioner, rather than a work of reference for the elucidation of doubtful and puzzling cases.

TUMORS OF THE OVARY, FALLOPIAN TUBE, AND BROAD LIGAMENT. By ALBAN H. G. DORAN, F.R.C.S. Pp. 189. London: Smith, Elder & Co. 1884.

DR. DORAN has collected numerous personal observations on ovarian pathology into a very instructive and readable volume. His book abounds in details of examination of specimens of the most varied kind. The whole domain of ovarian and tubal pathology is traversed. Nevertheless it seems to us that the practical value of his work might have been considerably enhanced by a more systematic presentation of the subject.

The author has observed well and much; why does he not save us the trouble of going through the detailed account of all his cases, by a clear and succinct statement of the conclusions that he has arrived at? It is true the reader is left to form his own conclusions; but that is precisely what the average reader wishes to be saved from doing. For the specialist this does very well, for the general practitioner very poorly.

THE ELEMENTS OF PHYSIOLOGICAL PHYSICS. An Outline of the Elementary Facts, Principles, and Methods of Physics, and their Applications in Physiology. By J. M'GREGOR-ROBERTSON, M.A., M.B., C.M. With 219 Engravings on Wood. Students' Manuals. Pp. 528. Philadelphia: Henry C. Lea's Son & Co. 1884.

THIS little volume is to physics what medical chemistry is to chemistry in general. It covers about the ground which professors of chemistry and physics take up in their lecture courses to medical students. It will, therefore, be found very useful to this class as being a condensed yet clearly written guide. It contains more than this, as the contents shows. This includes chapters on Electricity and Magnetism, The Graphic Method, Fluids at Rest and in Motion, Pneumatics, Optics, Sound, Heat, Dynamics. There is a good deal in the book regarding the mechanical appliances used in physiological experimentation and demonstration. This will be of great help to the student and physician, as it is not found in ordinary text-books on physiology or physics.

The Section on Electricity is long, and in the main a good one, but there is lacking a description of modern absolute galvanometers.

THE THERAPEUTICS OF THE RESPIRATORY PASSAGES. By PROSSER JAMES, M.D., Lecturer on Materia Medica and Therapeutics at the London Hospital Medical College; Physician to the Hospital for Diseases of the Throat and Chest, etc. New York: Wm. Wood & Co. 1884.

PROSSER JAMES has produced a scholarly treatise on the therapeutics of the respiratory passages, and the work will be studied with satisfaction, rising to admiration of the author, as the reader is made more fully cognizant of his object in writing a book of this character. It is not a compilation of what this and that authority thinks about the various diseases of the respiratory passages, and his pet formulæ for combating distressing symptoms. From beginning to end it is an exposition of what a physician, armed with modern diagnostic skill, can hope to accomplish by rational therapeutics in a most important and widely prevalent class of diseases.

The author does not use therapy in the restricted sense of enumerating the various drugs commonly employed in respiratory diseases, together with the indications for their use. Treatment with him means everything that may in any way contribute to the well-being, or rather better-being, of the patient.

The subject of food, for example, is fully considered in a separate chapter. "Aliments as Remedies" promoting construction are minutely discussed, and the fact clearly brought out that they are among our most potent remedial agents.

Exercise and rest, water, diluents, the various beverages, all receive careful attention.

The concluding chapters of the book deal with what the author calls "pneumatics," *i.e.*, expectorants, antiseptic and disinfectant pneumatics, antispasmodic, sedative, and anodyne pneumatics, methods of inhalation, and kindred subjects.

There is no question that Dr. James' book is the best treatise in the English language on the rational treatment of diseases of the respiratory passages, and, as such, the readers of Wood's Library will have reason to be thankful that the November issue is such an entirely satisfactory one.

THE ANALECTIC: A Monthly Periscopic Summary of Medical Science. Edited by Waller S. Wells, M.D. Vol. I. Royal 8vo, pp. 582. New York: Putnam's Sons. 1884.

As its title indicates this is a monthly summary of medical science. The first volume presents a creditable appearance, is filled with interesting and instructive facts in every department of medicine, and gives an excellent idea of the progress of medical science during the past year. The Editor has used rare judgment in his selections, and has succeeded in making an attractive and useful volume.

DENISON'S ANNUAL CLIMATIC MAP OF THE UNITED STATES. By CHARLES DENISON, A.M., M.D., Professor of Diseases of the Chest and of Climatology, University of Denver. Chicago: Rand, McNally & Co.

THE object of the maps is to show at a glance (by different colors) the degree of cloudiness, humidity, direction, and character of winds in all localities in the United States; the local rainfall; the mountainous elevations for sanitaria; finally isothermal lines, which latter experience very marked curves in the mountainous regions in the Territories. The coloring, red and blue, is vivid; the numerical figures large and plain; so that the busy practitioner can immediately place the finger on the desired locality where it is preferable to send his patient, and thus avoid the trouble of consulting other doctors. The newest lines of railroads are laid down, and the location of mineral springs given. As regards normal temperature lines, commencing say on the sea-coast, it is seen that the heat, going South, increases about a degree to every degree (inversely) of latitude. One large map is 53x32 in., exclusive of marginal tables. Four smaller maps show the various degrees of humidity and dryness observed during the four seasons; the data are taken from the official records of the Signal Service Bureau at Washington. The maps are bordered by numerous meteorological tables.

Dr. Denison is author of the "Rocky Mountain Health Resorts," "The Influence of High Altitudes upon the Progress of Phthisis" (International Medical Congress, 1876); and "Reports" to the American Medical Association on Climate of Colorado, and Consumption; and Committee of the American Climatological Association, acting with the Signal Office, on Climatic Elements, etc.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 11, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. W. H. PORTER presented, on behalf of a candidate, a specimen of *congenital malformation of the heart.*

DR. WACKERHAGEN presented a specimen of

CARCINOMA OF THE BREAST,

accompanied with the following history:

The tumor is a typical scirrhous carcinoma, with thick alveolar walls, and small alveolæ containing epithelial cells. Mrs. F——, forty-five years of age, born in Ireland, married twenty-six years; no children, no miscarriages; always regular until forty-three years of age; has not menstruated since. She has suffered more or less from malarial fever for the last five years. She first noticed small lump in left breast six months ago, which enlarged very slowly. She complained of no pain until about six days before the operation, when she suffered from burning and shooting sensations. The operation was performed on January 10th. The axillary glands (though not diseased) were removed, with a quantity of fat, from the axilla before removal of the breast. Strict antiseptic precautions were observed during the operation. The first dressing was removed on the fifth day, showing complete union of the entire wound. Highest temperature since operation, 99¼° F.; appetite good, and patient in excellent health.

HYDROSALPINX.

DR. P. F. CHAMBERS presented an ovary and tube which he removed at the Woman's Hospital on the 17th of last month, and in a condition of hydrosalpinx. The patient entered Dr. Thomas' service about the middle of December, and gave the history that eight years ago she began to suffer from pains in the pelvis, especially on the right side, and had had repeated attacks of localized peritonitis. On examination the left ovary could not be felt at all, but on the right side was found, as was supposed, a cyst of the ovary about the size of a hen's egg. During Dr. Thomas' sickness, Dr. Chambers performed the operation for its removal by the usual method. He found the ovary on the left side about one-fourth of its normal size, and firmly bound down. A cyst was distinctly recognized on the right side, and by careful manipulation it was raised without rupturing it, and a ligature thrown about it, when it was removed. On the tenth day the stitches in the abdominal wound were removed, and the patient recovered without accident.

The following report of the microscopical examination, made by Dr. Coe, pathologist to the hospital, accompanied the specimen

The ovary is small and shows hypertrophy of the fibrous stroma without marked cystic degeneration. The tube is as large as a small pear, and presents a regular enlargement from the uterine toward the distal extremity. The exterior is smooth and shows no evidences of adhesions. The walls of the tube are so thin that when held in front of a light the tumor appears translucent.

A probe may be passed through the cut end of the tube into the cyst, and by gentle pressure several drops of clear watery fluid can be pressed out. On microscopical examination this is found to contain numbers of ciliated epithelial cells, but no pus.

Closer examination of the tumor shows that at the site of the distal opening of the tube there is a distinct white cicatrix resulting from a probable inflammatory process, which led to obliteration of the opening. No trace of the fimbriæ remains.

The condition is one of *pure hydrosalpinx*, not due to parametritic inflammation, but to a strictly localized process, the cause of which is unknown.

DR. T. MITCHELL PRUDDEN presented microscopical slides, illustrating

THE COCCUS OF ACUTE LOBAR PNEUMONIA.

They showed the characteristic appearances described by Friedlander, who maintained that they were constantly present in the lungs of persons dying of this affection. Dr. Prudden had examined twenty-four specimens, and had found the coccus in the tissue of the lung in every instance. The micro-organism is about one-thousandth of a millimetre in diameter, ovoidal in shape, surrounded by a hyaline capsule, which is sometimes nearly as bright as the coccus itself, and the cocci appear either in the form of beads or chains. Whether causative or not of the disease had not been entirely settled. Dr. Prudden had also examined ten specimens of bronchopneumonia, occurring in children, and had found a coccus which presented the same appearance morphologically as that which he had found in acute lobar pneumonia in adults.

The characteristic features of the pneumonic coccus of Friedlander were the size, the peculiar form, but most of all, their physiological effects.

DR. H. MARION SIMS presented a specimen accompanied by the following history:

FIBROID TUMORS OF UTERUS—REMOVAL OF UTERUS, TUMORS, AND OVARIES.

Miss X——, aged thirty (born in England), consulted me in January, 1884. She gave the following history: Menses not at all regular for some months past. Last from six to twelve days, and occur again in eighteen or twenty days. Loses a great deal of blood, using as many as twenty-four napkins in twenty-four hours. Severe pain across abdomen for three or four days before menses begin. Feels weak and exhausted for several days after the period is over. Has severe pain at times over left ovarian region. Says she knows she has a tumor, but never felt any pain until a "lump" began to grow in the tumor. General health fair. Has to take iron tonics. First noticed the growths two years previously. Has increased in size about the abdomen during the past three or four months. Bowels regular.

Examination showed the uterus to be four and one-half inches deep, with three distinct tumors attached—a central and two side ones—very hard and not very sensitive to pressure. The uterus was not movable independently of tumors, but, as a mass, could be freely moved from side to side. I began by treating her with hypodermic injections of eight drops of the "ergotinine" of Tauret, administered in the abdominal walls two or three times a week. This had the effect of controlling the severe loss of blood, so that the menstrual flow came on once in twenty-four to twenty-eight days, and lasted only from three to six days. It had no effect whatever on the growth. Her general health improved rapidly. She became ruddy and much stronger. During my absence in Europe last summer the hypodermic injections were not continued, and on my return I found her in a worse condition than before, daily growing weaker, and the tumor on the left side of the uterus had grown so rapidly that it gave her a great deal of pain and inconvenience. An operation was advised, and readily acceded to, although several of London's most eminent surgeons had warned her never to have any operative interference. The usual incision was made, and the whole mass—uterus and eight distinct fibroid tumors—lifted up. Both ovaries were cystic and enlarged. The whole were gathered up in a bunch, and a rubber ligature firmly tied about the whole about on a level with the os internum. Skewers were then run crosswise below the ligature, so as to hold the pedicle firmly in position. The tumors, uterus, ligaments, and ovaries, were then cut through. Antiseptic dressing around stump and wound. The pedicle sloughed through on the thirteenth day, and came off, together with the skewers and ligatures. Highest temperature reached

was 102⅘°, and pulse never went above 114. It is five weeks to-morrow (February 12th) since operation, and patient is now sitting up all day, and walking about room.

THE RESULTS OF LONG-CONTINUED IRRITATION—EPITHELIOMA OF THE LEG EXTENDING TO MEDULLA OF TIBIA—SPONTANEOUS FRACTURE—SUPRA-CONDYLOID AMPUTATION.

Dr. George F. Shrady presented a specimen removed by supra-condyloid amputation of the thigh for malignant disease of the tibia and adjacent soft parts. The patient was a German, sixty-one years of age, who dated his trouble from the time he was eighteen years old. He then had a swelling over the tibia, probably caused by traumatism, which resulted in an abscess, and since that time he had been suffering from a sore on the leg, a period of over forty years. He was able to attend to his business, that of a clerk in a hardware store. During all this time the sore discharged more or less, but apparently did not increase in extent. One year after its first appearance he noticed a piece of exfoliated bone at the bottom of the ulcer. He got along with his simple ulcer until about two years ago, when the leg began to pain him so much that he was obliged to use crutches in walking. About one year ago the ulcer took on a new action, spread in different directions, penetrated the deeper parts from all points, and began to involve the tibia. The discharge changed from apparently healthy pus to a thin, sanious fluid, accompanied with frequent hemorrhages, sometimes so profuse that it was necessary to plug the openings to control it. About seven months ago he noticed a false point of motion, and it was then found that the tibia had begun to break down, and the evidence of malignant disease of the bone was very plain indeed. The ulcer at that time presented a ragged appearance, with everted edges and fungoid growths protruding from different parts of the base. There seemed to be no doubt concerning the character of the disease, which was believed to be epithelioma, although positive diagnosis was not made on account of circumstances preventing a microscopical examination before the operation. Carden's operation was performed on February 7th. Since the operation Dr. Shrady had had opportunity to look at some sections of the growth, and they were unquestionably epitheliomatous in character. The disease had apparently progressed from the skin, and involved the medullary cavity of the bone. The case seemed to have been one in which the disease began as an ordinary periostitis, followed in turn by necrosis, limited caries, also a limited osteomyelitis. Finally, from long-continued irritation, the ulcer took on a malignant tendency, epithelioma developed and progressed, and at last involved the medulla. The epithelial growth extended above and below the point of local manifestation. At the time of the operation Dr. Shrady was convinced that the disease involved nearly, if not the whole, of the medulla of the tibia, and he, therefore, performed the supra-condyloid amputation. Dr. W. H. Porter had made sections of the specimen, which showed the diseased parts, and it appeared that the tarsal bones had not been involved; but the infiltration of cancerous material had extended into the head of the tibia. The compact tissue of the bone was of course not involved.

Dr. Shrady had never seen a similar case, and considered it a rare one.

The following pathological report was made by Dr. W. H. Porter: "At the anterior and inner aspect of the leg, near the junction of the middle and inferior third, there was a deep ulcer having irregular walls. The morbid process had completely destroyed at this point four centimetres of the tibial shaft. The compact substance of the tibia was thin and soft when compared with a normal bone. The medullary cavity, on both sides of the excavation, was invaded by the diseased process for several centimetres. The disease had not involved the tarsal bones or femur except from atrophy.

"Microscopic examination: Scrapings were examined from various portions of the ulcerating surface. In every instance an abundance of epithelial cells was found, and often concentric masses in the centre of nests. Cut sections from several places, and from the involved medulla showed that the disease was of an epithelial nature, with a decided tendency to the concentric nesting diagnostic of epithelial carcinoma. In many cases there was an abundance of the prickle-celled epithelium. The growth is unquestionably an epithelial carcinoma.

Dr. Porter remarked that Billroth mentioned the fact that epithelioma might begin in the skin, develop and involve the bone, independent of origin of malignant disease in the bone itself.

Dr. Shrady thought that the case, and all belonging to this class, illustrated the necessity of operating early, if subsequent trouble from malignant disease would be avoided; probably, in this instance, if sequestrotomy had been performed several years ago and the ulcer had been allowed to heal, the malignant disease would not have developed.

Dr. Ripley thought it a question whether the disease was primarily epithelioma. It by no means followed that, because epithelioma developed secondarily, it was the primary affection. Many men had sores on their legs for forty years and did not get epithelioma; many men had had epithelioma and yet had not had sores on their legs for forty years; and it was also possible for a man to have epithelioma for forty years. As to whether an amputation performed some time ago would have saved the man subsequent trouble was a question.

Dr. Shrady believed that all that Dr. Ripley had said was quite possible, but that it was hardly probable. The point to be illustrated was that the disease began as a benign trouble, and in consequence of the continued irritation, in a system prepared for the invasion of cancer, the malignant disease developed.

The President had no doubt that malignant disease was in great part secondary to prolonged irritation, whether there was present any inherited tendency to the disease or not.

Dr. W. M. Carpenter remarked that he once heard Volkmann, of Halle, direct especial attention in a clinical lecture to the liability of apparently benign ulcers taking on a malignant tendency, and involving all the tissues beneath.

Dr. Porter remarked that when Dr. Satterthwaite and he were gathering material for their report on cancer, some time ago, the conclusion which they reached was that long-continued local irritation was one of the exciting causes of cancer.

ERYSIPELAS FOLLOWING INCISIONS IN THE SKIN FOR THE RELIEF OF ANASARCA — CHRONIC PERICARDITIS — CHRONIC VALVULAR DISEASE OF THE HEART—PHYSICAL SIGNS.

Dr. John H. Ripley presented a specimen accompanied with the following history: C. C——, twenty-seven years of age, a native of France, and a painter, was admitted to St. Francis' Hospital, January 10, 1885. Family history showed neither phthisical nor cancerous taint. The patient had been a hard drinker until six months ago. No specific history could be obtained. He was admitted to the hospital in May last, suffering with some pain in the region of the heart, and at that time the diagnosis of mitral insufficiency and acute parenchymatous nephritis was made. The patient was discharged, improved, June 18, 1884. When admitted last month the patient complained of pain in the region of the heart, and had noticed that his feet were swollen at night. The swelling of the feet had existed about a month, and for three weeks he had had a slight, but irritating, cough. On admission his face was pale and œdematous, his skin was

slightly jaundiced, and there was pitting on pressure over the chest.

Lungs: Slightly high-pitched percussion note on both sides, front, and behind. High-pitched, moist râles in abundance, and a few sibilant and sonorous râles on both sides. There was one loud musical râle heard through the entire respiratory act on both sides; more marked in front than behind. There were some friction-sounds on both sides of the chest.

Heart: Increased area of præcordial dulness, apex beat diffused and displaced one inch to the left, and one and one-half inch below the nipple. Epigastric pulsation was marked. Four murmurs were present: first, a systolic murmur, heard with greatest intensity at the apex, and conveyed posteriorly; second, a systolic murmur, heard with greatest intensity at the base, and transmitted along the large vessels; third, a diastolic murmur, heard with the greatest intensity at the xyphoid cartilage, and circumscribed; fourth, a slight prolonged friction-sound at the junction of the second rib with the sternum on the left side.

The liver was small, and there was ascites. There was also hydrothorax. There was general anasarca. The patient suffered from dyspnœa, orthopnœa, had total loss of appetite, and his pulse was rapid, irregular, and feeble. But little relief was afforded by internal medication. Dr. Ripley made several punctures in the skin about the malleoli, and a few on the inner aspect of the thighs; two or three in the scrotum. The result was leakage of a large quantity of water, and the patient improved rapidly for two weeks; his appetite was restored, and he was able to lie down, etc.

One clinical feature which he noticed particularly was the marked œdema of the left arm and hand, although the patient did not recline particularly upon the left side; the right arm and hand were only slightly œdematous. Dr. Ripley made a few punctures in the hand, which allowed considerable fluid to drain away. Subsequently erysipelas developed in this region.

The points which he wished to make in the case were the following: First, concerning the effect of the punctures. Some two or three years ago this question was brought before the Society by the present Secretary, who asked him after the report of a case in which punctures had been made, what had been his experience with regard to the development of erysipelas after making such openings in the skin; and Dr. Ripley said he had not seen erysipelas follow the operation. Since that time he had had this point in mind, and this was the second case in which he had seen erysipelas follow punctures of the skin for the relief of general anasarca. In the other case, erysipelas followed soon after the punctures were made, and probably was caused by them; but in this case the punctures had entirely healed before erysipelas developed. It was doubtless true that, in a certain proportion of this class of cases, erysipelas would develop whether the limbs were punctured or not, and it was well known that such incisions in the skin constituted one of the most valuable means at our disposal for the relief of extensive anasarca.

In the second place, as could be seen from the specimen, this was a case of chronic pericarditis, as the pericardium was bound down to the heart throughout its whole extent, except at one place, and it was at that point where the slight friction-sound was heard during life. The pericardium was also adherent to the anterior wall of the chest. Dr. Ripley had noticed in other cases, also, œdema of the left upper extremity associated with chronic pericarditis.

The heart was immensely hypertrophied and greatly dilated, the aortic valves were thickened, shrunken, and stiff; the mitral orifice was the seat of marked stenosis, and the valve was very much thickened. Yet there was no presystolic murmur heard during life, which was another interesting feature of the case. The left auricle was immensely dilated.

Next, with regard to the apex-beat in cases of adhesions of the pericardium, Dr. Loomis had stated that when there was adhesion of the pericardium to the walls of the heart, and also to the chest-wall, the apex-beat would be found above its normal position, and not displaced to the left. In this case, the apex-beat was displaced both downward and to the left. It seemed from this case, therefore, evident that no certain rule could be given which was applicable to this class of cases. The position of the apex-beat would depend on the size of the heart, whether or not it was hypertrophied; also, the position in which it was at the time the adhesion took place, whether it was displaced by fluid in the pleural cavities, or in the pericardium itself.

Dr. Van Santvoord thought that Dr. Ripley's remarks concerning the infrequency of the presystolic murmur should not be passed without some comment. He thought it was true that this murmur was the one which disappeared most readily during quietude of the heart, but to say that it was infrequent in cases of mitral stenosis, he thought, was a little too strong a statement. Another well-recognized point, with reference to this murmur, was the fact that it frequently presented itself rather as a prolongation of the first sound of the heart than as a distinct murmur. In this particular instance, the patient had a very dilated, weak heart, and it was not unreasonable to suppose that, when lying in bed, the heart would not give any murmur. But when mitral stenosis occurs as an independent affection in persons otherwise quite vigorous, the presystolic murmur certainly was very frequently recognized.

With reference to œdema of the left arm, he had presented to the Society a specimen of acute pericarditis, in which œdema of the right arm had occurred, and without œdema affecting the left. In that case there was no local cause for the disease.

Dr. W. H. Porter had seen two cases in which diagnosis of mitral obstruction was made, based upon the existence of a presystolic murmur, and the diagnosis was confirmed by the autopsy. In one case the mitral orfice admitted only one finger. With reference to the presystolic murmur, he had always argued that it was not before the first sound; that the systolic act commenced in the auricle, and that the presystolic murmur was produced at the last end of the auricular contraction, and caused by obstruction to the current of blood going into the ventricle.

Dr. Ripley said he did not intend to convey the idea that the presystolic murmur did not occur. He simply made the statement that it was a murmur of very infrequent occurrence, and based the statement not only upon a very large personal experience and observation in hospitals, but also the observations of one of his colleagues, who was a very competent observer. It was also based upon the statement of Leaming, who was recognized as a most competent observer, and also upon the writings of Quincke. With regard to the cases referred to by Dr. Van Santvoord, he would ask if they were not clinical cases.

Dr. Van Santvoord said that many of them were clinical cases.

Dr. Ripley remarked that in a great many of such cases diagnosis of mitral stenosis was made, based upon the existence of a presystolic murmur, which was not verified when the autopsy was made. In some of those cases stenosis had been diagnosticated and regurgitation had not been made out, which was something rather peculiar.

Dr. Gerster asked Dr. Ripley whether he meant to infer that erysipelas was of frequent occurrence without the presence of other lesions of the skin.

Dr. Ripley said that he certainly was of the opinion that the occurrence of erysipelas after puncture was not of frequent occurrence.

Dr. Carpenter remarked that when he brought the question before the Society it was simply for the sake of

inquiry. It was the result of an observation made by an old country physician, who himself was the subject of general anasarca dependent upon cardiac disease, and he asked that his limbs be punctured notwithstanding the liability to the occurrence of erysipelas, because he wished to receive the relief which would follow drainage of fluid from the extremities. At his earnest solicitation the punctures were made, erysipelas followed, became phlegmonous in character, gangrene occurred, and the doctor died within a week from the time the punctures were made. He had frequently asked the question concerning the occurrence of erysipelas after punctures in this way, and had uniformly received the answer that the occurrence had not been observed.

Dr. Gerster referred to the fact that cases of chronic localized dermatitis, dependent upon disturbance of the circulation of the skin, occurred from time to time without any considerable cutaneous lesion. This was not erysipelas, although it might be accompanied by high fever and a peculiar temperature which was found in that affection; it rarely reached a phlegmonous condition or abscess.

Dr. W. H. Porter mentioned a case where openings in the skin occurred spontaneously in a case of general anasarca from chronic nephritis, and erysipelatous inflammation developed in both extremities, which terminated in gangrene and death of the patient apparently by septicæmia.

The President thought the cases in which erysipelas followed such punctures occurred chiefly in hospital practice. He had not seen any case of erysipelas or pseudo-erysipelas follow the punctures alluded to.

Dr. Porter referred to the fact that he had made several autopsies in cases of extensive chronic pericarditis, and in which there was no œdema whatever of either upper or lower extremities.

(To be continued.)

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ST. MARY'S HOSPITAL AND ITS MEDICAL SCHOOL—FORMER TEACHERS—NOTES FROM THE MEDICAL WARDS—DR. BROADBENT ON HEART DISEASES—A CLINICAL LECTURE ON ACUTE DILATATION OF THE HEART.

London, February 14, 1885.

St. Mary's Hospital is the youngest of the metropolitan hospitals having medical schools attached, having been founded by men many of whom are still living. Until recently, too, it was a small hospital, having only about two hundred beds. It has within the last few years been considerably enlarged. It now has accommodations for two hundred and seventy in-patients, though, owing to want of funds, it cannot yet receive this number of patients. A new and improved out-patient department was added in 1883, of which I sent you some account at the time, and the medical school buildings have been much enlarged. Its staff has been considerably strengthened within the last few years, and it now has complete and efficient special departments in all branches. It bids fair to become one of the most popular schools in the metropolis. Its success as a school has doubtless been greatly aided by its favorable location, situated as it is close to Hyde Park, and within an easy walk of the most fashionable parts of the West End.

Although its career has as yet been but brief, St. Mary's Hospital Medical School has numbered among its staff some names well known to fame. Among those deceased may be mentioned Sir James Alderson, Drs. Tyler, Smith, and Murchison, Messrs. Baker Brown, and George Gascoyen. The following gentlemen were also formerly connected with it and are still living: Dr. King Chambers, Dr. Farquharson, M.P., Mr. Samuel Lane, and Mr. Ernest Hart. The latter gentleman, now editor of *The British Medical Journal*, was formerly Ophthalmic Surgeon to the Hospital and Dean of the Medical School.

I have recently had the opportunity of observing the medical practice at St. Mary's Hospital, and perhaps a few notes on the same will interest your readers. I have more particularly watched the practice of one of the physicians—Dr. Broadbent. Dr. Broadbent, although now the senior but one of the physicians, is still comparatively young in years, and, in spite of a very large and increasing private practice, one of the most active members of the teaching staff. He has become one of the best-known among West End physicians, and has made researches in many branches of scientific medicine. He has original views on many subjects which he does not hesitate to formulate, and of which a good number have gained general acceptance. I propose more particularly now to refer to some of his views on heart diseases, reserving for a future letter some *résumé* of his teaching on diseases of the nervous system.

In teaching his pupils physical examination of cardiac cases, Dr. Broadbent rebukes those who adopt the superficial plan of placing the stethoscope at once over the heart, listening, and simply naming the murmur which they hear. He insists that the stethoscope should not be allowed to touch the chest until the position of the apex-beat has been ascertained by palpation, the force and extent of the impulse decided, percussion employed, and the pulse has been felt. He emphasizes the importance of the latter as a means of making a preliminary diagnosis. With regard to murmurs, he remarks that a murmur does not necessarily indicate a lesion. An aortic systolic murmur is not rare, whereas an actual narrowing of the aortic orifice is, he believes, far from common. Many of our text-books place an aortic systolic among the least serious of cardiac murmurs, but Dr. Broadbent teaches that where an actual narrowing of the arterial orifice has occurred the prognosis is grave. But this is not to be necessarily inferred from the existence of a murmur.

As regards the prognosis of a valvular lesion, Dr. Broadbent remarks that mere loudness of a murmur tells you nothing. The condition of the heart, as to hypertrophy or dilatation, is, of course, important, and also the state of the circulation generally, and especially the characters of the pulse.

In aortic regurgitation, the severer the lesion the greater is the hypertrophy and the lower the apex-beat. An important diagnostic point is the loss of the second sound in the neck. Aortic regurgitation is more dangerous late in life because there is no compensatory hypertrophy. When occurring in young people compensatory hypertrophy may enable them to live for years.

Dr. Broadbent lays especial stress on the importance of the pulse in a case of aortic regurgitation. When, in addition to the aortic diastolic murmur, other murmurs are also present, a careful observation of the pulse may greatly assist in deciding which is the most important of the lesions present. A pulse not very collapsing in character would indicate that the regurgitation through the aortic orifice is not, in a complicated case, the most important feature.

Last week I heard Dr. Broadbent deliver a clinical lecture on "Ante-dilatation of the Heart," in which some interesting points were referred to. Dr. Broadbent began his lecture by remarking that we are too apt to put the size of the heart as constant and changing only slowly. Having observed the apex-beat at a given spot, we are apt to regard that position as constant. We are apt to regard murmurs in the same way and to expect them not to vary. But they do. Pulmonary murmurs vary a good deal. So do tricuspid murmurs. Mitral murmurs vary the most, especially presystolic. Even an aortic regurgitant murmur sometimes disappears, especially

when it is the result of dilatation of the aorta above the valves.

We must distinguish between distention and dilatation of the heart. In the former case its cavities are overfull, but will return to their normal dimensions on the removal of the cause of their distention. Not so in dilatation. The process has gone further, and the walls have yielded. This is more frequent in the case of the right ventricle. All violent exercise causes distention of the right heart. It is some time before the right heart succeeds in transmitting the blood as rapidly through the lungs as it is brought to it by the veins. This is being out of breath. But if we begin running gently, or have good powers, we get our second breath. Then we get a transference of dilating power to the left heart. But the left heart is not so apt to be distended by violent exertion as by long-continued exercise. Great distention of the left heart is more serious than similar distention of the right. Dr. Broadbent remarked that when, on a Swiss mountaineering trip, he got very much out of breath while toiling up a tedious slope, the guide asked him simply if his limbs were all right or not, and on receiving his reply in the affirmative went on without taking any notice. It was, remarked Dr. Broadbent, a case of right heart *versus* left.

He enumerated the following as symptoms and signs of dilatation—acute or chronic: Embarrassment of the circulation varying from mere shortness of breath to dyspnœa, orthopnœa, dropsy, apoplexy, etc., varying according to which side of the heart is affected. On the right side the symptoms are those of venous obstruction, on the left side those of deficient propulsion of blood from the left ventricle. The apex is displaced downward, outward, or in both directions. The apex-beat is diffuse and ill-defined over a large area. There is often a slight tap in place of a distinct heave. Increased dulness on percussing the cardiac area is noticed.

We ought, said Dr. Broadbent, to have made a provisional diagnosis before listening with the stethoscope. The sounds are short at the apex, but scarcely so sharp as in mitral stenosis. They are loud unless degeneration of the heart-wall has occurred. The second sound is reduplicated at the apex. The interval between the two sounds is often affected. The interval is either increased, so that the two sounds are equidistant, or else the opposite extreme is reached. Spacing of the interval is more common and less serious, and means that the ventricle takes longer to overcome the obstacle to its contraction. The other would mean either increased power of the ventricle or lessened peripheral resistance, but these are out of the question in dilatation. Really it means that that ventricle cannot go through its systole at all. The pulse may be regular or irregular. It is full between the beats, compressible, but its distention suddenly ceases.

The causes of distention are either a distending force or muscular weakness. We may have dilatation when the walls are healthy. Muscular weakness rarely causes acute distention. More commonly the two causes are combined.

Dr. Broadbent remarked that cases of acute dilatation of the heart might be arranged in two classes: 1. Those in which dilatation of the heart is a mere incidental feature of the disease. 2. Those in which acute dilatation of the heart is the prominent symptom.

In cases belonging to the first of these groups, acute disease is an important cause of cardiac dilatation. In pyrexia the heart is weak and the pulse one of low tension. There are two groups of acute diseases in which dilatation is common: 1. In all acute pulmonary affections. The prognosis in these affections turns very much on the power of the heart. In these cases the physical signs of dilatation are not easily made out. In bronchitis the lungs overlap the heart, and in pneumonia or pleurisy we have to distinguish the dulness from that cause. In these cases there is a great contrast between the laboring heart and the feeble pulse. Venesection is beneficial in such cases. 2. Acute renal disease. Every case of acute Bright's disease gives us acute dilatation of the right heart.

CONCERNING MALARIAL AFFECTIONS OF THE EAR.

To the Editor of The Medical Record.

Sir: My letter to which Dr. Pomeroy refers in his paper, "Affections of the Ear Influenced by, or Dependent on Malaria and Defective Drainage," published in the issue of The Medical Record of January 31st, was, if I remember correctly, written about a year ago. Since that time I have, through the courtesy of friends in general practice, and at my request, been afforded opportunities for seeing a number of patients suffering from malarial troubles; and it is chiefly with the view of supplementing my observations in the aforesaid letter, that I desire to ask space for this communication.

Dr. Pomeroy furnishes the opinions of a number of capable aurists wisely addressed in different and widely separated parts of our country, and they neither negative nor positively favor the idea of a malarial cause of ear disease; however, certain cases have been so carefully detailed in our literature by observers who are accustomed to weigh evidence, which must be accepted as proving, if nothing more, that ear disease may be influenced by a malarial agency.

The following case bears upon the subject of Dr. Pomeroy's paper. A man, aged thirty-five, a music-teacher, consulted me August 21, 1883. He had had "chills and fever" very often, a few years before I saw him. Had had pharyngitis for a long time antedating any noticeable lowering of hearing power. Never noticed that his hearing was any worse during paroxysm of fever, but his "throat always troubles him most when the fever is on." Had taken quinine, but never in large quantities at a time. For about three years he had had loud noises in his ears, like "whistle and drum;" was very dizzy at times. For the past two weeks, nearly every day he had been attacked with vertigo; falls to the ground and vomits, then sleeps for about an hour. This condition of things has incapacitated him for work, and it is on account of the last-named symptoms rather than the defective hearing, that he asked my advice. His general health is not good; although of large frame and muscular, he is anæmic and nervous, and dyspeptic. Both drum membranes are very much depressed and adherent to promontory. H. D. R. E., watch not heard ad conchem; L. E., watch heard ad conchem only. Tuning-fork tests are indicative of middle-ear trouble. Only left ear could be inflated, but inflation did not improve hearing. Had two attacks of vertigo yesterday, August 23d, the last of which lasted for half an hour; but he did not vomit after the attack. August 24th, air exhausted in external auditory canal, after which tinnitus stopped for a few moments. The tinnitus was not affected by small doses of quinine: large doses increased it. For some time before January, 1884, the vertigo had been stopped entirely in consequence of treatment directed to the middle ear, but there still remained slight tinnitus aurium. After patient's last visit in January, 1884, I lost sight of him until the following June. I found that he had been having intermittent fever for several weeks, for the relief from which he had taken some proprietary medicine, but without benefit. His general health was very bad.

For a week before consulting me this time he had suffered from severe pain in both ears, and this pain was most severe every other day; the pain being accompanied by a feeling of malaria and bodily heat, but there was never any elevation of bodily temperature on these occasions. Examination of the ear revealed a slight injection of both drum-membranes and external auditory canals near the latter; he had several bad molars on each side, but they did not ache. Quinine neither in small nor

large doses relieved the pain in the ears, but when combined with morphia there came relief; leeches had been applied to the tragus, but they did very little good. Small doses of quinine and iron frequently repeated, with a liberal allowance of whiskey and nourishing food, soon showed their good effects, and patient made a slow recovery with marked improvement in his hearing power, the middle ear having, of course, received appropriate treatment.

This case is interesting as showing that apparently ominous symptoms may owe their origin entirely to a diseased condition situated in the middle ear, and also to the effect, I think, of a malarial agency as a modifying influence in otitis media: but this is certainly not malarial otitis. In the two instances, among *two hundred and twelve malariai patients* with ear trouble, in which I believed a remittent fever to be responsible for a striking modification in the ear affection, pharyngitis had in each instance existed for some time previous to the fever attack, and the inflammatory reaction in the middle ear was associated with an active pharyngitis.

From what I have been able to gather from my own observations, and those of general practitioners familiar with the examination of the ear, and therefore competent judges, ear trouble in malarial fever is very infrequent, and that form of inflammation of the middle ear, described by Weber-Liel,[1] and which he named *otitis intermittens*, has never been met with by any of those physicians with whom I have placed myself in correspondence, in parts where "malaria" is very prevalent. And "*otalgia* intermittens," first described by Voltolini,[2] and Weber-Liel[3] is uncommon.

Weber-Liel regarded the affection of the ear as a real inflammation; Voltolini, on the other hand, laid greater stress upon the neuralgic symptoms, and called it otalgia intermittens. According to Weber-Liel the affection usually presented itself with all the objective and subjective symptoms of acute catarrhal otitis, and with fulness in the head, noises in the ear, and pain in both. The peculiarity of the disease consisted in its intermittent character. Regularly at the same hour the pain would begin, increase in intensity for a certain length of time, and subside after a certain period, and like the pain, so all other symptoms, subjective and objective, would show free intermissions at first, and marked remissions during the pain of the disease. In some cases the pain was ushered in by a slight chill. On the third or fourth day the membrana tympani was perforated, this being followed by a discharge from the ear without relief to the patient. The ordinary treatment of catarrhal otitis proved of no avail, the disease lasting many weeks and months, and ultimately even affecting the mastoid cells. The use of quinine (?), however, arrested it at once and achieved a speedy cure.

My own cases ol acute otitis media, occurring in the course of intermittent fever, certainly were favorably influenced by treatment directed to the supposed malarial agency, but this alone was never, in my experience, sufficient to cure the disease; however, the neuralgic form was positively benefited by quinine, but even then the addition of an opiate was a desideratum.

The affection of the ear met with in this class of cases, and supposed to be characteristic, belongs to that variety of catarrhal otitis which runs its course without marked inflammatory reaction, and has its starting-point in the pharyngeal mucous membrane, and, when marked inflammatory reaction occurs in the middle ear in the course of an attack of intermitteut fever, it should, I believe, be regarded as coincidental. Middle-ear trouble has always pre-existed in such cases. However, it is not difficult to appreciate how repeated and long-continued attacks of intermittent or remittent fever may so impress the general economy and lower its vitality as to furnish the necessary elements for the exhibition of the subjective and objective symptoms detailed by Weber-Liel, Voltolini, Green, and Hotz, and these words apply particularly to the suppurative otitis media, which has been referred to a malarial origin, the analogues of which may be seen in those cases of eye disease occurring in certain forms of fever, and which were first described by Hewson (1814), Wallace (1828), Mackenzie (1843), and more recently by Reich,[1] Paul Knipping,[2] Bernard Lachmann,[3] Suchhau,[4] and J. Trompettin.[5] But the eye affection in these cases has nothing in itself characteristic of the disease with which it is associated. The same objection applies to the term malarial otitis, which would imply a specific action on the part of the "malaria."

The city of Canton, in tropical China, is an interesting region in which to study the effects of malarial fevers and a vitiated state of the atmosphere (see my letter in this journal, July 8, 1882, "Medical Impressions of China") in the production of catarrhal affections. There, the mischievous element which induces "the malarial" manifestations seems to be the exposure of the body, especially during the night, to moist air, in the natives' low, damp buildings. There is a complete absence of sanitary arrangements in the homes of these people, and affections of the mucous surfaces, especially those of the eyelids and pharynx, are very general. Of eight hundred Chinese, whose ears I examined during a journey across the Pacific in 1882, there was not a single instance in which some form of middle-ear trouble and pharyngitis did not exist; and these conditions have always pre-existed in all of the recorded cases of so-called "malarial otitis," or "otitis intermittens."

In this particular class of cases that treatment will be the most judicious which is addressed to both the general condition of the patient and that of the middle-ear. I think that large doses of quinine, frequently repeated, do more harm than good in acute otitis media. If a patient have intermittent fever in addition to an otitis, I begin with quinine, five to ten grains, and follow it up with one to two grains every hour or two during the day; but I do not think it of any benefit to continue the use of quinine long after the apparent recovery of the patient.

I am sure that every one who is interested in this subject will be instructed by a careful perusal of a case of middle-ear disease influenced by malaria (but not malarial otitis) described in great detail by Dr. Roosa, of this city, in the recent edition of his "Treatise on the Diseases of the Ear," pages 321 to 326, and which reflects in a striking manner this writer's keen sense in dissecting symptoms and selecting those particular signs which justify the diagnosis made.

JOSEPH A. ANDREWS, M.D.

40 WEST TWENTY-FOURTH STREET, NEW YORK.

HOW TO OBTAIN CLINICAL MATERIAL WITHOUT IMPOVERISHING THE YOUNG DOCTOR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The question who is and who is not a proper person for dispensary relief requires very careful thought. It is necessary that action be taken to prevent further indiscriminate medical charity. In considering this subject, there are two things that must be borne in mind, as their proper appreciation should influence whatever is done to remedy this growing evil.

We have in this city the largest medical schools in America and the best teaching faculties. New York is the metropolis of the country, and the colleges will always have full classes of students anxious to take advantage of the hospitals and clinics. For instruction material must be provided.

[1] Klinische Monatsblätter f. Augenheilk., 1875, p. 487.
[2] Deutsche Archiv f. klin. Medizin, 1880, vol. xxvi., p. 10.
[3] Ebend., vol. xxvii., p. 526.
[4] Virchow's Archiv, vol. lxxxii., p. 18.
[5] Klin. Monatsblätter f. Augenheilk., 1880, p. 123.

From our commercial relations and our cramped position on a narrow island, we have a great many poor. The crowded condition of our tenements (New York has more than three times as many inhabitants to a house than has London), bad hygiene, and social surroundings increase the number of the poor. The foreigners who now come to our city are not the stout, strong immigrants of years gone by, but are a poorer order, almost paupers, whose occupations, if they have any, have been hitherto almost unknown to us. With an increase in age, we have the second and third generations of people who approach in habits and surroundings the scum of European cities.

For the colleges we have to propose a more systematic, careful manner of securing clinical material. The dispensaries should be grouped, so as to contribute to the needs of the classes. The colleges *will* have cases, and it is best that they should utilize the dispensary material, rather than take cases from the young practitioner, who suffers by the present method of bidding for patients.

The people who apply for dispensary or out-door aid should understand that their cases will be investigated by the Charity Organization or any similar society. Those who can pay a modest sum should be formed into clubs, managed under the rules of the dispensaries, from among whose physicians they could choose their own attendant, to be paid by the dispensaries for each case attended.

An effort must be made to limit the number of dispensaries. The managers of a dispensary should be the proper ones to decide whether the district it covers is in need of any other institution. It is well known that these places of indiscriminate relief, started by mistaken philanthropists or ambitious doctors, if even for some specialty, can hardly keep in the narrow path, but spread out, and soon all the inhabitants of the blocks around are dispensary patients, and thus they are gradually pauperized by being taught to be improvident, as they can always go to the dispensary or hospital when sick. Advice is cheap; talk costs nothing. Groceries they pay for, but for attention to their health these people give seldom a curt thank you.

Great is the fault of the doctors as well as of the public, but something can be done to prevent the increase of this careless system, or want of system, of medical charity.

WALTER L. CARR, M.D.

36 WEST THIRTY-SECOND STREET, February 28, 1885.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 21, 1885, to February 28, 1885.

PATZKI, JULIUS H., Captain and Assistant Surgeon. Leave of absence further extended seven months on surgeon's certificate of disability. S. O. 40, A. G. O., February 17, 1885.

PERLEY, H. O., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect about March 5, 1885. S. O. 16, Department of Dakota, February 10, 1885.

ROBINSON, S. Q., Captain and Assistant Surgeon. Relieved from duty at Fort Spokane, W. T., and ordered for duty as Post Surgeon, Fort Klamath, Oreg. S. O. 23, Department of Colorado, February 5, 1885.

KEAN, J. R., First Lieutenant and Assistant Surgeon (recently appointed). Assigned to duty at Fort Sill, Ind. T. S. O. 23, Department of Missouri, February 11, 1885.

BENTLEY, EDWIN, Major and Surgeon, relieved from further duty at Fort Clark, Texas, and assigned to duty as Post Surgeon, Fort Brown, Texas. S. O. 17, Department of Texas, February 16, 1885.

TAYLOR, M. E., Captain and Assistant Surgeon, assigned to duty at Fort Stanton, New Mexico, as Post Surgeon. S. O. 29, Department of the Missouri, February 21, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 28, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
February 21, 1885.....	0	12	90	6	111	74	0	0
February 28, 1885.....	0	4	91	2	158	53	0	0
Deaths.								
February 21, 1885.....	0	4	14	5	27	31	0	0
February 28, 1885.....	0	2	20	2	25	21	0	0

CORRECTNESS IN DIAGNOSIS.—There are some men who can never learn to aim or fire at a case. Regarding their diagnosis the safest place is to get behind them and trust to luck that the gun is not heavily enough charged to kick. Such marksmen generally do best when they shoot in the dark and use scattering shot.

GIVING THE YOUNG MAN A CHANCE.—*Anxious parent to old consultant*—Tell me, confidentially, doctor, do you think Dr. Young understands my son's case? *Doctor*—Perfectly, my dear sir. I have rarely seen so much talent in one so young. No man is better read in his profession, or has used his opportunities to better advantage. I wish I had had them when I was young. He spends all his time in study. All he wants now is practice and experience to make him a great man. *Parent*—But has he any experience in these cases? *Doctor*—Really, I am surprised, under the circumstances, at his judgment and skill. Indeed he is modest to a fault, and is more open to conviction of error than any young man I have met. In all my large experience in these cases I have never seen one handled better. *Parent*—But, doctor, we would like you to take charge of the patient. *Doctor*—That would be impossible. I have too much business already, and, besides, he has called me in consultation, and I could not attend this particular case.

A PESSIMISTIC VIEW OF THE THERAPEUTICS OF CHOLERA.—Dr. D. B. Simmons, who has had a large experience in the treatment of cholera in many of the countries of Eastern Asia, from Japan to India, does not entertain a very hopeful view of success in the management of the disease should it visit our land. He is frequently asked what is the best treatment of cholera, and says that he is accustomed to preface his answer with the following statement: "The statistics of the late epidemic in Europe furnish a mortality of fifty per cent. My own statistics of the mortality in Asia give the same average rate of fifty per cent. In the former case the majority of the patients received treatment directed by men well informed concerning all the remedial agents known to modern scientific medicine. In the latter class, however, not one patient in a thousand was seen by physicians of the western school. In fact great numbers of them were not visited by the doctors of any school, preferring to put their trust in charms and prayers to their various divinities, having from long experience had quite as much reason for belief in the curative powers of one as of the other. I take it for granted that it is not necessary for me to add the moral to the above."

INFORMATION WANTED.—A correspondent writes to inquire whether any valuable results have been obtained in the use of cocaine in the cure of the opium habit, and, if so, what is the best manner of employing it?

ANTIPYRIN.—M. Dujardin-Beaumetz states that antipyrin is sometimes adulterated with quinine and sugar. Its price in this city has been about twenty to thirty cents a drachm.

PHOSPHORUS IN RACHITIS.—Both Professor Henoch and Dr. Baginsky report unfavorably on the use of phosphorus in rachitis, and they have given it a trial in many cases. The discussion of the subject has occupied much time in the medical societies here of late.—*Berlin Cor. Archives of Pediat.*

BACTERIA FROM THE SOIL TO THE AIR.—Brantlecht is said to have demonstrated that bacteria may be transferred from the soil to the air. He moistened ignited sand, clay-like garden soil, and a gravelly soil with liquid containing bacteria, and covered each with a glass bell. In a few hours the moisture condensed on the sides of the bell was found to be swarming with the same forms of bacteria.

SPRAY IN OVARIOTOMY.—Dr. John Homans, of Boston, writes: "The following is an extract from a recent work by Dr. Emmet (Emmet's "Principles and Practice of Gynæcology," p. 715): 'In this country I do not know of any prominent operator who now employs the carbolic acid spray.' This statement implies that the writer is not persuaded of the value of spray in ovariotomy. My own experience has led me to an opposite opinion. Indeed, I should not like to do a laparotomy for any purpose without antiseptic spray. I have been led to this conclusion by the results of one hundred and eighty-three cases of removal of cystic ovaries, of which I have lost only twenty-one; but more especially by the result of the last one hundred of these cases, only ten of which were fatal, while thirty-eight were consecutively successful. I feel that to omit the antiseptic spray would be to deprive the patient of one of the ready and efficient elements of success. As I can hardly hope for much better results than those I have cited, and being quite content to let well alone, I shall hesitate before disturbing my present plan of operation by giving up a detail to which I attach much importance."

MURIATE OF AMMONIA.—Nothnagel is celebrated for his scepticism about medicines, but he says the alkaline carbonates and salts are best employed in chronic catarrhal affections of the mucous membranes, notably in chronic catarrhal gastritis, and in that complex of symptoms known as the status gastricus, marked by loss of appetite, bad taste in the mouth, nausea, sometimes even vomiting, belching of gas, a feeling of pressure, fulness over the stomach, and a more or less coated tongue. The question, whether to use soda or muriate of ammonia, can be decided in favor of the latter when there is also a non-febrile bronchial catarrh present in its second stage; while soda is to be preferred when there is considerable irritability of the air-passages and an urgent desire to cough. Muriate of ammonia is to be preferred in bronchial catarrh when the fever has passed away, or the first severe febrile symptoms have disappeared, and there is only difficulty of expectoration. It is also followed by good effects in pneumonia when the crisis of the fever has passed; when there are few râles and only whistling and rattling sounds are heard, while expectoration is still difficult. It may also be given when the expectoration stops, in consequence of an acute relapse, or exacerbation of the inflammation.

FATAL POST-PARTUM HEMORRHAGE ON EIGHTH DAY —ADHERENT PLACENTA AND HOUR-GLASS CONTRACTION.—Dr. W. E. Irvin, of South Carrollton, Ky., attended a poorly nourished woman in a long and difficult labor. By podatic version and use of the forceps a dead child was at last delivered. The cervix was torn on one side, and the patient had an adherent placenta with hour-glass contraction. The placenta was stripped off and hemorrhage ceased. The woman did well until the fourth day when she had diarrhœa, which our correspondent thought might be septic. It yielded, however, to bismuth and opium. On the eighth day hemorrhage set in. The first attack was controlled by ergot, brandy, kneading, and cold. Ten hours later, hemorrhage came on again, and the patient died before the doctor reached her. Dr. Irwin says: "I am now of the opinion that the nervous system was overwhelmed by septic matter absorbed through the lacerated cervix, and in the future I shall guard against this danger by antiseptic injections in all instrumental cases. I say *instrumental* labor, because I do not believe in the antiseptic injections in *all* cases of labor." Dr. Irvin says that he has had at least twenty cases of adherent placenta in the past two years, and in these cases, and these alone, he finds hour-glass contractions.

PREGNANCY IN A WOMAN FIFTY-ONE YEARS OLD.—Dr. F. N. Burgess writes: "I delivered a woman recently aged fifty-one years, three months, ten days, of a healthy male child. Last confinement, ten years and a half previous."

DECOCTION OF VALERIAN AS A SEDATIVE.—M. Martel, the principal surgeon at the hospital at Saint Malo furnishes Dr. Arragon, of Paris, with some facts concerning the use of the decoction of valerian as a sedative. A patient was brought in with both hands and a part of the forearm crushed by a threshing-machine. Fever was absent, but the agony was great. The wounded region was dressed with an antiseptic dressing of carbolic acid. As soon as it was deemed prudent the following decoction was used in the dressing to replace water: Forty grammes of the root of valerian to a litre of water, boiled for half an hour, then strained, and ten per cent. of carbolic acid added to it. After its application all pain disappeared. The wound became clean and healthy; all the symptoms were most satisfactory. Dr. Arragon adds that country people in Normandy often use the decoction of valerian to calm pain in the case of wounds and fractures.—*Brit. Med. Journal.*

THE THERAPEUTIC EFFECT OF THE SOLANACEÆ IN OSCILLATING SPASM OF HEAD FROM LIGHTNING SHOCK.—Dr. G. F. Harvey, of Parsons, Kan., referring to Dr. Eggleston's paper on "Atropia in Severe Electric Shock," relates the history of a pertinent case of his own. A robust, hard-working young woman, three months pregnant, received an electric shock from a bolt of lightning, which struck a plough a few paces distant. For the next two months she was confined to her bed most of the time. Her symptoms were a constant rhythmical rolling of the head from side to side, at the rate of seventy-five to one hundred times a minute. This kept up more or less day and night. It was accompanied with much pain, which greatly exhausted the patient. Treatment had been "irregular," and had done no good up to the end of the two months, when she was brought to Dr. Harvey. Our correspondent writes: "Not knowing what else to do, I left fluid extract of hyoscyamus and atropiæ sulphas, with instructions to give it until sleep occurred or its physiological effect was produced. About a week after the husband reported, to his and my surprise, that no more of the symptoms had occurred since taking the hyoscyamus mixture, and during the month the patient was able to bear the journey of ten or fifteen miles travel to town, although unable to walk steadily without assistance. I left the State shortly after, and when next I heard of this case, indirectly, the account was the 'movements' had gradually returned, and after her confinement they had become almost as bad as ever. I think this would have been a good case to try the effect of the method of local compression with the steel collar recommended by me some years ago in neck chorea. The object in reporting this is to corroborate in a small way Dr. Eggleston's observation of the good effect of the 'Solanaceæ' in affections of the nervous system from shock."

The Medical Record

Original Articles.

RESULT OF OPERATIONS FOR THE REMOVAL OF TUMORS FROM THE BLADDER.

BY ALEXANDER W. STEIN, M.D.,

SURGEON TO CHARITY HOSPITAL (GENITO-URINARY DIVISION); PROFESSOR OF PHYSIOLOGY AND VISCERAL ANATOMY AT THE NEW YORK COLLEGE OF DENTISTRY, ETC.

RECENT writers comment on the "decided impetus which the surgical treatment of tumors of the bladder has received in late years." Yes, when we consider for how long a time these growths have been allowed to have their own way, the interest now manifested in this direction is truly remarkable. In some instances in the past the bladder has been actually opened, and yet no attempt was made for the removal of an existing tumor. Perhaps the earliest example of this is recorded of Petit, of whom it is said that, although he did not remove the polypus, the operation of opening the bladder was not attended with any bad result, but a year afterward the patient died, and the autopsy revealed a polypus the size of a *fist*, of a pyramidal figure, and attached by a *very delicate pedicle!* In several operations of lithotomy of more recent times it is stated that after the removal of the stone a vesical growth was found, *but not interfered with*. The interest manifested in this subject is apparent not only in the number of lectures and monographs that have been published during the past three years, but also in the number of operations that have been recorded during this time as compared with preceding times.

Previous to December, 1881, I could find but forty-five operations recorded.[1] Since that time I have found fifty-three. The following table will show the contrast at a glance:

Males: First period, extending from 1830 to December, 1881 (fifty-one years), 13 operations (of these 2 recorded since January, 1882); second period, extending from December, 1881, to January, 1885 (three years), 40 operations.

Females: First period, extending from 1784 to December, 1881 (ninety-seven years), 32 operations (3 recorded since January, 1882); second period, extending from December, 1881, to January, 1885 (three years), 13 operations.

Total operations to January 1, 1885: First period, 45; second period, 53. Total, 98.

Operations on males.—The male bladder has been made accessible for the removal of tumors by the following methods, named in the order of frequency: 1, External perineal urethrotomy; 2, perineal cystotomy; 3, hypogastric cystotomy; 4, hypogastric and perineal cystotomy jointly; 5, hypogastric cystotomy and perineal urethrotomy.

External perineal urethrotomy.—External perineal urethrotomy has been performed 31 times. By Thompson 18 times, by Whitehead 4 times, by Bontecou twice, and by Watson, Morris, Morgan, Rauschenbusch, Harrison, Godlee, and Roddick. In four thirteen months to three years, in four six months to eleven months, and in nine a few days to three months elapsed since the operation.

From these figures we learn simply that out of thirty-one subjects seventeen were living at the time the operation was reported. If, however, we enter into a closer examination of the condition of these patients, we find that very few indeed can be regarded as having recovered in the true acceptation of the term. In five at least it is distinctly stated that the growth was only partially removed, hence recovery or permanent relief is not to be expected. In some other cases the relief was decided, but temporary, the symptoms recurring after a longer or shorter interval of time, while in still others the operation is of too recent date to admit of any positive statement as to ultimate result. Fourteen cases terminated fatally: one within a few hours, two within a few days; three within a few weeks, and eight within a few months. For these fatal cases three principal causes may be assigned: 1, Incomplete removal of the growth—in all the fatal and unfavorable cases the tumors were attached by a broad base—sessile; 2, old standing and serious pathological changes in the urinary tract, especially the kidneys; 3, malignant disease.

Perineal cystotomy.—Perineal cystotomy has been performed ten times, by Covillard, Dessault, Crosse, Gersuny, Kocher, Humphry, Davies-Colley, Hill, Rauschoff, and Little. With one or two exceptions these operations were by the lateral method. Kocher opened the urethra by a T-shaped incision, a vertical cut in the mesial line and a horizontal one, after Nelaton's pre-rectal method. Of these ten patients six were reported recovered, three died, and of one recent operation we have no data. In regard to the deaths, the case of Hill should not militate against the operation, for this was not done with any hope of effecting a cure, but simply to afford temporary relief from intense suffering due to malignant disease in a subject sixty-three years old, already worn out and cachectic. The case of Gersuny was very exceptional, in that the tumor was inclosed in a diverticulum of the bladder and was altogether beyond reach, besides there were other serious changes in the vesical walls which even in the event of the successful removal of the tumor would have rendered recovery impossible. The patient, of course, was a child two years old, and the growths, of which there were a number, were only partially removed.

Hypogastric cystotomy.—This operation has been performed eleven times on ten subjects by Marcacci, Trendelenburg (twice), Bazy, Guyon (five times, twice on same patient), Küster, and by Sonnenburg. This enumeration does not include Liston's successful removal of a cyst. Marcacci sutured the bladder, the remainder were treated by the open method. In regard to the patients of Küster and Sonnenburg we require further data, but recovery is scarcely to be expected in the latter case. All the others terminated fatally. In the patient of Marcacci the cause of death was imperfect closure of the vesical wound. This was brought together with catgut ligatures and the abdominal wound with metallic sutures. Patient did well at first, but died within two months from extravasation of urine, pelvic abscess, and peritonitis, because, as Marcacci thinks, of the too early absorption and destruction of the catgut sutures, which probably lost their holding power before the union of the wound had become firmly established. The question might be asked, whether, when the imperfect closure of the bladder was first manifest by the appearance of the supra-pubic urinary fistula, the fatal complication might not have been averted had the bladder been opened and drained through the perineum?

In at least five instances the growths were malignant

[1] A Study of the Tumors of the Bladder. By Alexander W. Stein, M.D. William Wood & Co.

—Bazy, Trendelenburg, Guyon (two), Sonnenburg. In the other case of Trendelenburg the cause of death was extensive kidney disease, lung abscess, etc. In the two remaining cases of Guyon (one probably also malignant) the patients died in a few days from exhaustion. In four of the cases—although malignant—a remarkable amelioration of symptoms was noted after the operation. One lived six and a half months, another three months, another nearly two and a half months, and then submitted to a repetition of the operation, dying on the third day subsequent thereto, a fourth lived two months, and a fifth one month.

Hypogastric and perineal operation.—Twice has access been made to the bladder jointly through the perineum and above the pubes: First, by Billroth, suprapubic and lateral peritoneal cystotomy; second, by Volkmann, supra-pubic cystotomy and external perineal urethrotomy. The first patient, treated by the open method, recovered. The second died, apparently because of the imperfect closure of the vesical wound, which was attempted by suture. Death occurred on the third day from peritonitis and diffuse purulent infiltration of subserous areolar tissue.

Resection of the bladder.—Sonnenburg relates the case of a female aged sixty. The urethra was dilated and a tumor was detected on the anterior wall of the bladder, which afterward proved to be a fibro-sarcoma. He made a supra-pubic cystotomy and removed the anterior wall of the bladder, leaving only the lower portion and sphincter intact. The peritoneum, which had to be opened during the operation, was sutured and the bladder drained both through the abdominal incision and urethra. Nearly *four weeks* had elapsed, there had been no fever, wound was granulating on all sides, and the general condition of patient was satisfactory. We have no further data as to the termination of this most unpromising and daring operation, but it is at least suggestive of possibilities.

Females.—In the female, owing to the shortness and dilatability of the urethra, tumors may be removed by this channel with comparative ease and safety. If the tumor is not accessible, or is too large to admit of removal after bloodless dilatation of the urethra, the canal may be further enlarged and shortened by incision. Sometimes the tumor will be reached more readily by kolpo-cystotomy. If the situation and attachment of the growth is such that it should be seen to be properly manipulated, a **T**-shaped incision of the vesico-vaginal septum will enable the operator to invert the vesical walls, bring the growth into view, and perform a dissection with almost as much facility as on the surface of the body.

Forty-five operations have been performed for the removal of growths from the female bladder—37 by urethral dilatation, 8 by incision of the urethra or of the vesico-vaginal septum. The subjects varied in age from nineteen months to seventy years. Of the 37 patients from whom the growths were removed by urethral dilatation, 24 recovered (I include in this number the patients of Guillon, Bishop, and Godson, in whom, though the result is not distinctly stated, the phraseology is such that there can be little doubt as to their successful termination), 3 cases are reported as much improved by the operation, and 10 terminated fatally. The fatal termination may be assigned to: First, in at least five instances to malignant disease; second, imperfect removal of growth; third, kidney disease. It should further be noted that four of these unfortunate subjects were children, aged respectively nineteen months, twenty-two months, two years and nine months, and five years.

After the eight cutting operations five recovered and three died. In regard to the question whether the surgical interference was in any of these cases immediately responsible for the fatal termination, we can note but one instance, that of Senftleben, to be referred to below. As to the size and character of the growths that have been successfully removed through the urethra, some are given as the size of a goose's egg, turkey's egg, tennis ball, etc., which have been removed by simple torsion and avulsion, by ligature, silk and catgut, silver-wire, by écraseur, knife, Pacquelin, and by scooping out with a sharp spoon. As showing what can be done in the least promising of cases Simon successfully scooped out from the walls of the bladder a sessile growth that had occupied two-thirds of the cavity of that viscus.

The tumors removed in both sexes have included papillomata, myxomata, myomata, sarcomata, and epitheliomata. It is not the purpose of the present study to enter into the details of the various methods of surgical interference for the removal of vesical growths from the male bladder, our object at present is to ascertain if possible what are the prospects in this field of surgery, and, at the same time, form some judgment of the relative advantages and disadvantages of each of the foregoing operations. To do this we must not be guided simply by the percentage of recoveries or of deaths as given, but must examine minutely into the conditions which, in each procedure, favored success on the one hand, and the causes which determined the fatal termination on the other. Thus, each procedure will rest on its own merits, and the conclusion will, I think, be inevitable that the selection of an operation cannot be a matter of choice, but must depend upon the location, mode of attachment, and size of the growth to be removed. A disposition to routine practice is manifested, especially in favor of the simple and easily performed external perineal urethrotomy, a most valuable operation, indeed, but one which has scarcely justified the sanguine claims of its devotees. The evidence before us seems conclusive that sessile growths are not manipulated to advantage through a perineal opening, especially when the growth is located in the upper region of the viscus, or on its anterior or lateral walls. And the impression is irresistible that a number of our unfortunate cases would have terminated successfully had the bladder been opened from above, the only procedure which could have afforded in them any hope of success.

It has been observed that in very fat subjects with deep perineum and in cases of prostatic hypertrophy and lengthening of the prostatic urethra, a very serious difficulty presents to the satisfactory exploration of the vesical cavity. Again, we have to contend against the danger of working in the dark. This is illustrated in the accidents met with by Senftleben and by Stroinski, both of whom lacerated the bladder in their manipulations through the dilated female urethra (a more accessible route to the bladder than through the perineal opening). Senftleben attempted the extirpation of a sarcoma, he endeavored to seize the base of the tumor with forceps and draw it out, but this did not succeed, and because of the great friability of the tumor it had to be removed piecemeal; its broad base, however, could not be so removed. Patient died on the fourth day after the operation from purulent peritonitis. On examination there was found on the right side of the fundus a perforation large enough to admit the index finger. In the case of Stroinski the tumor, about the size of a walnut, of dense fibrous structure, had a short and dense pedicle, the bladder was lacerated by the twisting and traction made on the growth. The laceration was on the anterior wall, and Stroinski saved his patient by, as far as I know, a unique procedure. He made a complete inversion of the bladder through the urethra, discovered the rent, two centimetres long, and applied three carbolized silk sutures. The reduction of the bladder was effected, a catheter was kept *in situ* for two weeks and the woman entirely recovered.

On the other hand, external perineal urethrotomy, as the simplest, least hazardous, and, of the perineal operations, the most direct route to the cavity of the bladder, will always remain a favorite operation as a means of diagnosis, if nothing more. Evidence pointing to the

existence of a tumor in the wall should lead immediately to the performance of an external urethrotomy. Once such an opening made, if the growth is within reach and is removable, it will be so treated; if it proves to be inaccessible or too widely attached to the vesical walls to be thus removed, and supra-pubic cystotomy is found necessary, the perineal incision will not diminish but rather increase the chances of recovery by affording free drainage for the urine in the most depending position (adopting drainage by suction).[1] In Billroth's case the preliminary perineal incision proved eminently satisfactory. The number of failures in supra-pubic cystotomy should not discourage us nor should they militate against a repetition of the operation. This operation has shown excellent results for the removal of stone, and if its record is not correspondingly good for tumors, it is because the growths attacked were of malignant character, or because the operations were too long deferred. It is reasonable to assume that some of the latter cases would have terminated successfully had the operation been undertaken at an earlier period. For the removal of certain forms of tumor the fact that the parts are freely exposed to view and to manipulation is an advantage that must supersede every other consideration.

The dangers apprehended from supra-pubic cystotomy are twofold—wounding the peritoneum and urinary extravasation. The former is avoided by distending the bladder above the pubes, or, what is more practicable, elevating it by means of a colpeurynter per rectum. The prevention of urinary infiltration involves the consideration as to the best way of dealing with the vesical wound. Shall it be stitched or shall it be left open? Both methods have shown excellent results, and in both the main question involved is thorough drainage, in the one by means of the urethra or perineum, in the other through the abdominal wound, combined or not with urethral drainage. Trendelenburg[2] inserts a T-shaped drainage-tube in the bladder and placing his patient in the abdominal decubitus or on the side, by means of air-cushions, etc., elevates the pelvis sufficiently to obtain a descending direction to the outflow of urine.

Vidal de Cassis suggested dividing the supra-pubic cystotomy into two separate operations; the first to consist in making the abdominal section down to the bladder and some days after the establishment of surrounding adhesive inflammation to open the bladder. In some cases clamping the lips of the vesical incision between those of the abdominal wound may be found practicable.[3]

Finally, let us bear in mind two facts: First, tumors of the bladder, if uninterfered with, necessarily terminate fatally, death resulting either from cachexia, hemorrhage, or from the effects of mechanical obstruction to the outflow of urine; second, the results thus far attained by surgical interference are most encouraging, and in every way justify a repetition of the same.

With regard to the treatment of malignant growths there is no reason why a timely operation may not in some cases prolong life. But while amelioration of symptoms may be anticipated in some old-standing and unpromising cases, we should seek to operate early. The least suspicion of the existence of a tumor should lead to an investigation, that, if present, it may be removed while the general condition of the patient is yet favorable for an operation, before he has become exhausted from the loss of blood, or the kidneys and bladder have become so much diseased as to make recovery impossible even in the event of the successful extirpation of the growth.

THE ETIOLOGY AND TREATMENT OF NASAL CATARRH, WITH SPECIAL REFERENCE TO THE DEVIATED SEPTUM.[1]

By WILLIAM CHAPMAN JARVIS, M.D.

LECTURER ON LARYNGOLOGY AND DISEASES OF THE THROAT IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE.

Few diseases have, until in recent years, at least within the last decade, occupied a more obscure position as regards their pathology and therapeutics than those involving the nasal passages. Such, as is generally acknowledged, being the case, it is not surprising that chronic nasal catarrh should be classed among the "opprobria medicinæ," giving rise to the somewhat general impression that it is an incurable disease. It seems to me to be our duty as medical men to determine whether this belief is based upon the reliable testimony of carefully conducted scientific investigation, and if not to promptly condemn the circulation of such an erroneous opinion.

In pursuance of a line of inquiry, recommended by me in 1880,[2] I will seek the solution of this unsettled question by discovering and removing the cause and effects. In 1882[3] I extended this line of thought and considered more in detail the part played by the deviated septum in nasal catarrh, accentuating as in the first paper, pressure irritation produced by contact of the septum with the turbinated tissues. I also gave my grounds for attributing chronic rhinitis to this and defective nasal drainage and finally offered novel remedial methods for dealing with the deflected septum.

In order to simplify and at the same time systematize the description of this deformity, I have for several years employed a classification which, at least, possesses the merit of simplicity, in addition to other advantages already enumerated by me.

Deviation of the septum narium may obviously be either, in character, osseous, cartilaginous, osseo-cartilaginous, or hypertrophic: In form these varieties may be either localized, that is, limited to small portions of the septum, or general, involving the whole extent or a large surface of the septal structure. I cannot discuss here my reasons and right for employing so simple a classification, suffice to say for the present it accords with the various conditions, and has afforded me an excellent guide for the surgical management of these conditions.

Osseous deflection of the septum rarely occurs alone, being almost invariably associated with the cartilaginous form, namely, osseo-cartilaginous. Long-standing deviated septa always exhibit hypertrophic changes over their most prominent points. These changes are due to pressure against structures lying opposite, *i.e.*, the turbinated bones. By far the most frequent form of deviated septum is the cartilaginous variety. As regards the question of the manner in which the deviated septum plays the part of a cause, I would ask attention to two most prominent and common factors, accounting for the production and persistence of the catarrhal processes in the majority of cases, namely, pressure irritation and defective nasal drainage. Farther on I shall have occasion to show that these conditions are also traceable to other important underlying causes of a more or less direct nature. The part played by pressure irritation in the causation of rhinitis hypertrophica I described in a paper read before the American Laryngological Association, session of 1880.[4] My deductions were based upon the careful and continuous study of a case exhibiting a frequent pathological condition, consisting of a thickening of the mucous membrane overlying the posterior borders of the vomer, shown in this drawing, taken from a life sketch (Fig. 1). I was persuaded that the hypertrophied tissues

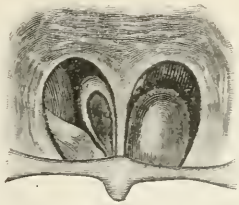

Fig. 1.

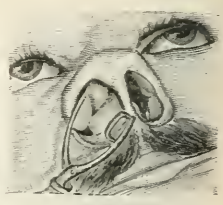

Fig. 2.

were caused by pressure of the turbinated structure lying opposite. This impression was received by my observing that the shape of the tumefaction was cup-shaped, and that the depression corresponded in shape and size with the convexity of the nearest turbinated bone. At times the depression was entirely concealed by the temporary impaction against its surface of a congestive turbinated hypertrophy. Retraction of the erectile structure soon revealed the mischief it had wrought by persistent contact, or in other words, by prolonged pressure irritation.

Do not understand me as attributing any particular pathological importance to this condition. I only consider it of value as proving the existence of a special determining factor in nasal catarrh, namely, pressure irritation.

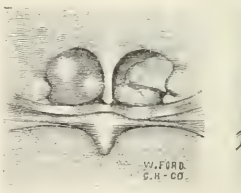

Fig. 3.

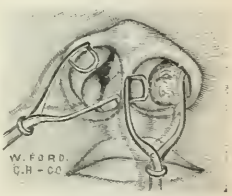

Fig. 4.

The drawing (Fig. 2.), taken from a life sketch, exhibits the action and effects of pressure irritation. The right anterior naris shows the deviated tissue pressing against the opposite turbinated structure. In the right posterior naris (Fig. 3) is seen the result—a post-inferior turbinated hypertrophy, almost entirely occluding the choana.

The next drawing (Fig. 4) was taken from a life sketch, showing an antero-inferior turbinated hypertrophy in the left nostril, caused by the combined catarrhal extension, and respiratory irritation from a deviated septum closing the right nostril.

I will now consider the second etiological factor, mentioned by me—defective nasal drainage. All intelligent observers must have been impressed with the fact that the peculiar inclination and semi-ovoid form of the nasal floor subserved a useful purpose, namely, that of a gutter for the efflux of nasal secretions and accretions. This view, described by me several years ago, has steadily gained ground in my mind until I find myself this evening prepared to present it in a more elaborate and favorable form.

This diagram (Fig. 5), built up from drawings of the normal structures will enable you to trace with me the nasal discharges from their origin, through the pharynx and gullet, until, with the salivary and buccal secretions, they find their way into the stomach. The heavy, dotted lines represent the course of the nasal fluids. Beginning at the anterior portion of the nasal gutter, the nasal mucus streams slowly downward over the easy convexities of

[1] Read before the New York Academy of Medicine, March 5, 1885.
[2] Archives of Laryngology, vol. ii., p. 147.
[3] Archives of Laryngology, vol. iii., p. 300.
[4] Loc. cit.

the turbinated bodies, and striking the nasal floor, gravitates backward along its gradual incline toward the posterior nares and pharynx. Posteriorly it is prevented from oozing down along the uvula and dripping into the larynx or pharynx by a slight elevation of the mucous membrane over the palate, which I have denominated the palatine prominence (*prominentia palatina*). This peculiar ridge-like elevation (Fig. 5. *pp*), beginning at the lower edge of the vomer and extending backward to a point just over the uvula, has, as far as I have been able to ascertain, been assigned no special function; the absence of this constant condition, in numerous drawings of the posterior nares, is a familiar example of its oversight. An attack of acute uvulitis, with obliteration of this palatine prominence, and consequent discharge of mucus into the larynx and pharynx, will convince one of its value in the economy of the throat. After leaving this point, the nasal fluids stream down, in a fan-shaped manner, along the pharynx, to the gullet. The discharges are prevented from falling into the larynx by the semicircular ridge formed by the arytenoid and Wrisberg prominences and their various folds.

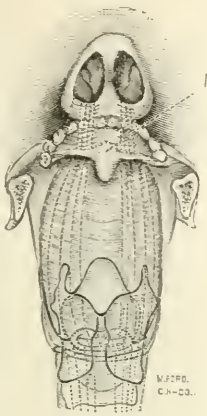

FIG. 5.

The importance of this system of nasal drainage is very clear, when one considers that it not only disposes of the natural excess in moisture, employed for olfaction, moistening the respired air, etc., but also is a means for the removal of the accumulations from the eye and accessory nasal cavities. This system once understood, it is easy to appreciate the consequences due to disturbance of its balance. Prominent among disturbing causes is the deviated septum. This interference, on the part of a deviated septum, is invariably associated with more or less turbinated hypertrophy. To these combined conditions are to be attributed most of the troubles due to defective drainage. Nasal mucus, of the proper specific gravity, readily finds its way into the stomach as just described. The obstruction presented by a deviated septum stops the nasal fluids on their way into the throat, the retardation leading to evaporation and consequent inspissation of the nasal discharges, producing the well-known train of symptoms, such as clogging of the nostrils, dropping of phlegm into the pharynx and larynx, etc.

The importance of pressure irritation and defective nasal drainage merits a more extended notice than I have accorded it, but the consideration of other causes which help to account for their existence urges me to leave it for the present.

Deviation of the septum can be traced as originating from certain well-defined causes, conspicuous among which I might mention heredity, traumatism, and acquired deviation of the septum.

Heredity.—In 1880 I reported[1] a case of congenital stenosis relieved by operation, in which was noted a peculiar malformation of the superior maxilla, and I sought to establish a relationship between it and the co-existing coryza and turbinated hypertrophies. Since then, by dint of close investigation and comparison, I have been able to supply the necessary links in a chain of evidence which demonstrates, at least to my mind, that one of the most common indirect causes of catarrh is to be found in the conformation of the hard palate. This peculiar malformation is transmitted from parent to offspring, and by its proper recognition we can at once account for the origin of a vast majority of certain cases of chronic nasal catarrh. Attention has been called, from time to time, to the various congenital conditions of the hard and soft palate, known as cleft palate, bifid uvula, etc. I shall, however, have nothing to say concerning these malformations. Several years ago a medical student, whom I was examining, called my attention to the great height of the roof of his mouth. I had been treating him for an extreme deflection of the nasal septum; the deviated structure was pressing directly against the left lateral nasal wall and had been in this position as far back as he could remember. I at once associated the high-pitched and narrow palatine arch with the bend in the septum, reasoning that inasmuch as the septum lay directly over the point of highest elevation, there must be a corresponding bulging of this structure, its amount depending upon the extent of encroachment of the elevated and contracted arch upon the nasal chambers.

Subsequent observations not only proved this inference to be correct, but also enabled me to trace the condition in many instances to its origin, the parent. These plaster impressions, kindly presented to me by Dr. Eddy, nicely illustrate this peculiar palatine formation. They were selected from among thirty other plaster casts, as the only two in which I could positively pronounce the existence of a chronic nasal catarrh. The doctor then referred to the name of the subject, who, happily for me, proved to be one of my old patients, afflicted with a severe catarrh, and almost forgotten by me. This was the only case of well-marked catarrh sent me by the Doctor, and both casts had been taken from the same patient.

On comparing this plaster impression (Fig. 6) with the normal palatine arch, you will readily discern certain

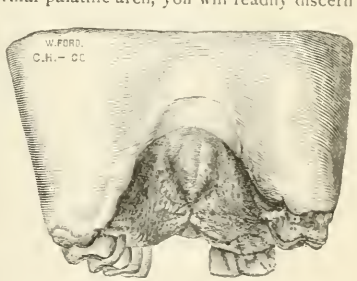

FIG. 6.

well-defined differences. The distance between the alveolar ridges is much greater in the normal specimen. The transverse diameter in the abnormal specimen is not only smaller, but its surface is markedly irregular.

The palatine arch may be considerably higher than this normal specimen, and yet not constitute a pathological condition. No two palatine arches are exactly alike, and some show an elevation readily mistaken for a deformity. The important distinction to bear in mind is the abrupt elevation along the line of the median raphe. When such a condition is observed, we may at once look for, and, in my experience, invariably find, a corresponding deviation of the septum.

Such, in numerous cases observed by me, has always proved the case, and the condition has been invariably associated with a chronic rhinitis. Indeed, I believe it is possible to diagnosticate the existence of a chronic nasal catarrh by the simple inspection of the roof of the mouth, or, what amounts to the same thing, an impression in wax or plaster sent from any part of the world. Having interested myself from time to time in the study of the external nose, and particularly in the persistence of certain types in the same family, I was induced to consider it a special hereditary manifestation.

By employing a similar method of reasoning to the internal configuration of the nares, I have been able to

[1] Archives of Laryngology, vol. ii., p. 105.

trace the same condition back to a common parental origin. This, in my experience, occurs as an hereditary manifestation with great constancy. Once the peculiar nasal type of the parents recognized, its modifications in the children is easily determined. Sometimes this condition, with the co-existing intra-nasal catarrhal processes, can be inferred or diagnosticated at a distance by the conformation of the nose and the alveolar borders of the upper jaw. Last year I was afforded an excellent example of this in the family of a physician, the facial expression of whose children I had the opportunity of observing at a respectful distance. I afterward became acquainted with the gentleman, and was consulted by him concerning a throat affection afflicting his wife. I surprised the doctor by not only diagnosticating the catarrhal troubles of his children, but also satisfied him that the peculiar shape of his hard palate accounted for the existence of the disease in his offspring.

A few days since I examined several members of the same family, all adults, the condition of whose nostrils I correctly diagnosticated through a single member of the same family, who happened to be my patient.

In this family the nasal asymmetry was very well marked, the septum in one instance being deviated to such an extent as to disturb the external symmetry of the nostril. All the young men, three in number, possessed the paternal nasal type and palatine arch in an exaggerated form. All have suffered with nasal catarrh, dating far back in the memory of the family, and, I am informed that an absent son, not yet examined by me, is severely afflicted with the same complaint. The patient, an engineer by profession, and a very intelligent individual, referred to me by Dr. J. L. Corning, stated, without giving me his name, that a physician had informed him that his condition was due to a scrofulous taint probably inherited from his father. This piece of news did not surprise me, since it was only a few years ago that a statement was made in this Academy involving a similar proposition; and just here I would like to emphatically express my disagreement with this too prevalent idea of a diathesis or specific constitutional taint being the determining factor in *the majority of those* suffering with nasal catarrh from childhood. Furthermore, the view that these manifestations, though not retraceable one or more generations, are nevertheless to be attributed to diluted syphilis of several preceding generations, seems to me even more unreasonable, and yet we find it mentioned in recent works on the subject and soberly discussed by physicians. Although scrofula and inherited syphilis are responsible for certain cases of catarrh, it is high time that these stigma, too often placed upon innocent and intellectual families, should be removed. I say intellectual advisedly, for it is my conviction that remarkable mental development is likely to be associated with a nasal catarrh.

It is well known that a marked increase in the dimensions of the cranial dome is apt to be accompanied by a contraction of the osseous framework of the face. A remarkable example of this kind lately came under my notice, in the person of a girl, aged sixteen, the daughter of a physically and intellectually enormous man. The father's head measured seven and three-eighths inches, and yet his large hat closely covered the head of his delicate little daughter. She, in other words, possessed the face and body of a child, with the head of a Webster. I was not surprised to find the contracted nares of this child the seat of extensive disease. If you compare these two sections taken from a wax cast, you will observe the high palatine arch of the father is markedly exaggerated in his daughter. I could cite numerous other instances in proof of the correctness of this view did time and space permit. From what has been said, I think I can safely say that early acquired nasal catarrh, instead of being of scrofulous or diluted syphilitic origin may in many cases prove to be an intellectual disease.

I will now briefly consider the second mentioned direct cause of a deviated septum, and indirect cause of nasal catarrh, namely, traumatism.

Traumatism.—The effects of injury as an etiological factor, are identical with those resulting from heredity. So much so is this the case that I am not surprised to find the bulk of easily discernible deviated septa attributed to blows of various kinds, for want of a better explanation. There is now but little excuse for such a mistake, for although the deviated septum of a malformed maxilla may be increased by injury, the discovery of such a condition, associated with the usual signs, furnishes reasonable grounds for the assumption that it is hereditary and not of traumatic origin. This inference is, of course, strengthened by the history of the patient. Traumatic deviation of the septum, though occasionally found in the higher strata of society is more frequently met with in low life, the exposure and recklessness of the latter class of individuals rendering them more liable to injury. As an example I might state that I have yet to discover the nostril of a prize-fighter or reckless sparrer unaffected with a chronic nasal catarrh. It matters little what may be their so-called powers of resistance, the strongest must as surely succumb to nasal catarrh as a child similarly afflicted from a button in the nose.

By acquired or induced deviation, the third variety mentioned by me, I include such internal agencies as prolonged intra-nasal pressure upon the septum, as produced for instance by turbinated hypertrophies, polypi, and various tumors, the action of foreign bodies, inflammatory infiltration, the frequent employment of the finger for freeing the nostrils, etc.

The indirect influence of the high-pitched palatine arch and deviated septum observed in the production of aural, pulmonary, and eye troubles, also gelatinous polypi, and other intra-nasal growths, and its interesting etiological relation to phthisis must be passed by for the present, with little more than a mere mention.

Treatment.—I shall conclude my remarks with a necessarily brief consideration of the treatment of deviated septa. Employing a modified scriptural paraphrase of Dr. Didama's, "and now abideth Physiology, Pathology, and Therapeutics, these three, but the greatest of these is Therapeutics."

In other words, just in proportion as the first two elements add meaning to the third, are they to be valued as aiding in the one grand effort to ameliorate the misery of mankind. To accentuate this point I may be permitted to recall a remark made by a distinguished anatomist, the late Dr. Darling, who several years ago, after encouraging me to enthusiastically converse upon certain pathological conditions observed by me in the nose, suddenly interrupted the conversation with the remark, "But do you cure your patients?" That, gentlemen, is the important question with all of us.

An experience derived from several hundred operations has convinced me that no single method can be fairly recommended or successfully employed to remedy all deviated septa. Assuming the correctness of the propositions embodied in my previous remarks, I shall discuss the treatment of the deviated septum, as a most common cause of catarrh. As with a button in the nostril, so that thorn in the flesh, a deviated septum, must be removed to cure the catarrh.

Since several instruments will be presented to your notice, I trust you will not interpret them as indicating dissatisfaction with any one method and recourse at random to another, but as providing against certain possible contingencies. The very structure and shape of the septum warrants this assertion. We may meet bone, cartilage, or mucous membrane. The bone will dull or break our knives, the rongeur-forceps may strip off and mutilate unnecessarily the mucous membrane, and either may unfortunately perforate the deviated cartilage. For opening the field of operation I employ my ring-drop nasal speculum, since in my hands it has proved the

best for painlessly and persistently dilating the nostrils. In the treatment of cartilaginous and soft structural deviations of the septum, I have for several years employed nothing more than my écraseur with transfixion needles. Instead of using the No. 5 piano wire originally recommended and introduced by me for the removal of turbinated hypertrophies, I employ No. 0 and 00 piano wires. The exclusion of the question of hemorrhage in operations by ecrasement, is an additional recommendation for the employment of fine wires, cutting like knives. The employment of the écraseur for this purpose must be invariably combined with the use of my transfixion needles. These needles (Fig. 7) require no special description. They are pointed like the ordinary glover's needle.

Fig. 7.

Four sizes are made, running from one to four inches in length. Each number has a straight needle and three others of varying curves. They are all furnished with a light, convenient handle.

The removal of cartilaginous and soft deviated tissues by ecrasement has been followed by most excellent results in my hands, and where there is plenty of time at the operator's disposal, it is to be preferred for this purpose.

It is often desirable to economize time, and in order to do so I have devised instruments with which I have most satisfactorily accomplished this purpose. They are essentially cutting instruments, and consist of a fenestrated cartilage forceps and trimming scissors. Their blades are made almost at a right angle to enable the operator to obtain a clear view of the field.

The cutting edges of the fenestrated forceps (Fig. 8)

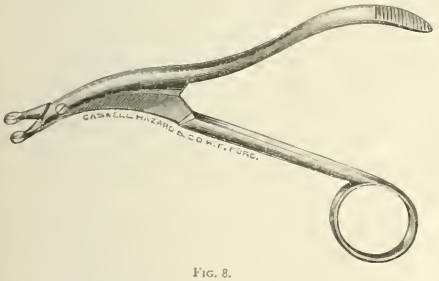

Fig. 8.

resemble somewhat, in shape and action, the ordinary ticket-punch. A ring on the fixed blade is intended to slip over the middle finger, and a knob on the free one is manipulated with the thumb. This arrangement enables one to seize and divide the cartilage with great facility. The trimming scissors (Fig. 9) are convenient for removing asperities remaining after the other instruments have been employed. The instrument is grasped like a pistol, firm pressure being exercised against its lateral margin by the index finger.

Thus far the instruments shown have applied only to cartilage and hypertrophied mucous membrane. Bone blunts or breaks their keen edges, and we may have to treat an osseo-cartilaginous deviation of the septum.

This little instrument (Fig. 10), essentially a rongeur forceps, has, in my hands, most satisfactorily accomplished this result. Its two blades are hollowed to cut like the teeth of a rodent. The instrument has the proper nasal curve.

A great advantage possessed by this bone forceps is the control exercised over it by the operator. Each osseous projection can be distinctly distinguished over the edge of the upper blade and deliberately crushed away by the keen-edged cutting surfaces, and by a kind of gnawing process large sections of the bone are

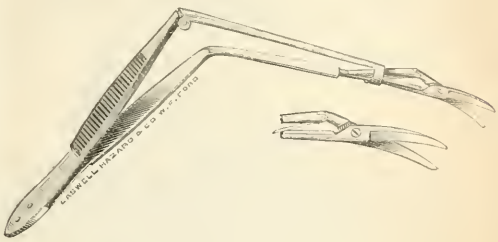

Fig. 9.

removed with rapidity and precision. All the methods thus far mentioned accomplish their purpose by removing the superfluous or deviated tissues or the turbinated structures opposite the deviated point.

Although this, in the majority of instances, can be accomplished without perforating the septum narium, or weakening the nasal supports, it is obvious that a certain class of cases, usually those presenting an extreme degree of deflection, may be followed by the above-mentioned undesirable consequences. I have, therefore, made it a rule to resort to a different method in this class of cases. This consists in the employment of Steele's stellate punch in conjunction with a peculiar nasal clamp or splint. Probably the least important feature of the operation is the cutting part, at least such a view is now current. The great difficulty rests in the proper approximation of the divided fragments, and just at this stage the bad results show themselves. While observing the behavior of a case operated upon and afterward treated by the usual method, the nasal plug, I was convinced that just here the trouble arose. From what I have already said, you will thoroughly appreciate the effects of such a foreign body lodged within the nostril. The intense irritation and secondary hemorrhage, profuse rhinorrhœa, high fever and inflammation, and general misery, is no exaggerated picture in my experience. Why, then, should we expect other than unfavorable results from the practice of this method? This little clamp has, in my practice, relegated these inconveniences to the history of the past. The septum, made sufficiently plastic by means of the punch, is simply held in place by a slight pressure

Fig. 10.

exercised over the cutaneous surfaces of the alæ nasi. No foreign substances disturb the equilibrium of the inner nares, and, therefore, the above undesirable consequences are avoided. The pressure of the splint can be nicely regulated by the patient by means of a delicate screw. Any tendency to loosen may be easily overcome by affixing adhesive plaster to the pressure-pads, and then sticking it to the skin.

This rhinometer (Fig. 11) is used for measuring the size and shape of normal and diseased nares.

Pain.—I will not weary you with more than a passing reference to cocaine. My experiences have been already recorded, with a series of reported cases.[1] I con-

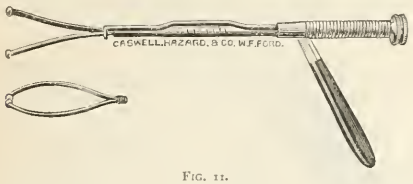

Fig. 11.

tinue to find it useful in operations on the septum, and consider it more effective when the displacement is situated well anteriorly, or less when deeper within the nares. Believing with Jebinek in the increased efficiency of concentrated solutions. I employ a ten per cent. preparation of Foucar's cocaine hydrochlorate. In spite of every precaution, extreme pain will be at times inflicted in a certain class of cases. In these instances I employ rhigolene in the form of a fine spray, with the same success as already reported by me. I have now been using it for more than a year. Pain is an actual impossibility when rhigolene is properly employed for this purpose.

The great and only objection to its use in the nose is the danger of an explosion. This I have effectually removed by employing an electric light isolated in a glass bulb. The carbon filament is rendered incandescent by means of Mr. W. Foster's electric cell. This cell is the same exhibited by me at the last meeting of the New York State Medical Society, and continues to prove highly satisfactory in my hands. It amounts really to a combined battery and secondary accumulator in a single cell, and runs without refilling for many months. Foster's portable mercury bisulphate battery may also be employed for the same purpose.

ILLUSTRATIVE CASES.

I shall very briefly report three cases selected as examples from a number of the same kind:

Mr. ——, from St. Catherine's, Canada; aged twenty. Referred to me, March, 1882, by Dr. W. H. Snow. Very much annoyed by constant accumulation of phlegm in throat and larynx, and by nasal stenosis. Examination: Post-inferior turbinated hypertrophy (bilat.), localized deviation of septum to left. Turbinated obstructions and deflected septum removed in twelve operations by means of transfixion needles and écraseur. The patient reported in person two years subsequent to the operations, pronouncing himself perfectly well.

Miss ——, aged nineteen, New York City. Referred to me in February, 1884, by Dr. J. Williston Wright, for a long-standing chronic coryza. Breathes at night through the mouth and suffers from other catarrhal complications. Examination: Complete occlusion of left nostril from an osseo-cartilaginous deviation of the septum with associated turbinated hypertrophies. Extraordinary elevation of the hard palate, traced back to the father, a life-long sufferer from catarrh. Successfully removed the hypertrophied and deviated tissues by means of cartilage and bone forceps. Reported six months afterward as free from catarrh and respiratory disturbances. The structures operated upon presented all the appearances of a normal nostril.

Dr. ——, New York State; aged forty. December, 1884. Complete occlusion of left nostril, with partial and increasing deafness. Extreme general deviation of cartilaginous septum to the left. Operated twice with Steele's forceps, using elliptical glass tubes and nasal clamp, with rhigolene and cocaine. Stenosis and pressure relieved. Decided preference given to nasal clamp and rhigolene. The good results reported as permanent.

25 East Thirty-first Street.

[1] The Medical Record, December 13, 1884.

ON THE CHOLERA OF EGYPT IN 1883, AND FRANCE, ITALY, AND SPAIN IN 1884.

By JOHN C. PETERS, M.D.,

NEW YORK.

I have read many brilliant essays of late on these topics, but not with unalloyed pleasure, for I believe that many writers have fallen into errors which it is important to correct. No really well-informed person has believed for a long time that carbolic alcohol will destroy the cholera poison; but many fully and correctly believe that real germicides will. It has been known since 1872 that microbes, bacilli, and bacteria could live in very strong solutions of carbolic alcohol, and that the dilute mineral acids, tannin, chloride, corrosive sublimate, and others would kill them.

In 1883 cholera did not arise alone in Egypt from filth, but from importation. It did not commence at Alexandria, but at Damietta, which is the nearest Nile port to Port Said, which is the outlet of the Suez Canal. These were 37,500 deaths from cholera in the Bombay Presidency in 1883. Bombay merchants came both to Port Said and Damietta to attend a great fair there, to which at least 15,000 people congregated, in addition to the 35,000 inhabitants. The barbers who shave and prepare the dead are the first registrars of vital statistics in many Egyptian towns, and the principal barber of Damietta was among the first to die of cholera; hence all the earliest records of deaths were lost, and the more fatal and infective diarrhœal cases were never recorded. Next the principal European physician of Damietta had his attention called to the rumors of numerous deaths, and investigated the matter to find that cases of cholera had occurred in May, whereas none had been reported publicly until June 21st. A *zadig*, or canal, runs through Damietta from one branch of the Nile to another, and this is the principal source of the water-supply.

Mosques and many houses are on the banks of this canal, and their drainage goes into it. Every mosque has a public privy, and also a tank for the ablution, which all good Mohammedans must use before entering a holy place. There was, of course, great choleraic water contamination, and a sudden outburst of cholera took place. The 15,000 people who came to the fair were stampeded out of Damietta, together with about 10,000 of the inhabitants, who carried the disease with them back into Egypt. Then only was a rigid quarantine established, and a cordon put round Damietta to keep everybody in, and let no one go out, neither food or medicines, or doctors, or supplies of any kind. Such is nearly the history of every town attacked in Egypt in 1883.

When the pestilence had been let out *en masse*, severe measures were taken to keep it in Cairo, for up the Nile was attacked long before Alexandria suffered. This cholera broke out, as it almost always does in Egypt, when the river Nile is low and the water unusually bad. It disappeared like magic, as it always does in Egypt, when the Nile rises and washes all impurities away. There had been little or no cholera in Egypt since 1865, and there had often been as much filth as in 1883. It has never become endemic there, as it is a rainless country, and generally too dry for the cholera germ to thrive.

Marseilles had a small outbreak of cholera in the fall of 1883, probably derived from Egypt, which she carefully concealed. In addition, cholera was also brought to Toulon from Tonquin by the Sarthe and other vessels. Toulon concealed her cholera for at least seventeen days, and did not confess it until it had got such headway that it could no longer be concealed. At least twenty thousand Italians fled from Toulon and Marseilles, and others were brought away in transports by the Italian government. Rome refused to receive any fugitives; Genoa and Naples welcomed them. There were at least three large importations into Naples. The

outbreak in Genoa was connected with washing soiled cholera clothes in one of the principal water-supplies of the city, and Naples has many privy-pits and surface wells. These privies, or *pozzis*, in the poorer parts of many Italian towns, are in the yards or cellars, and are so arranged that when they overflow the surplusage is carried through drains or gutters into the streets.

In the lowest parts of Toulon there were no privies at all, and the people emptied their chamber-pots into the streets every morning. This flowed down toward the harbor, which is almost tideless. Toulon always has much typhoid fever from this cause; but no cholera unless it is imported.

The great outbreaks of cholera in Paris in 1832, 1848, 1854, and 1865 have been explained at last by Dr. Marcy. The canal de l'Ourcq is one of the principal water-sources of Paris. The market-boats or vessels upon it and at La Villette are so numerous that Marseilles and Havre alone outrank it in shipping. The parts of Paris which are always most severely attacked with cholera, and where the most typhoid fever prevails, are supplied with this water, into which not only all the filth of the boats goes, but many sewers empty.

I agree with all that is generally said about civic filth favoring the spread of cholera, but it does not generate, but only supplies the pabulum for the germs. I believe as long as the Croton water is kept pure there can be no general outbreak of cholera in New York, only isolated cases, or at most a few in each house, and those only into which diarrhœal cases come, or soiled clothes are brought; that it will not spread even to the next house, and that there are no pandemic waves of cholera.

I think it impossible to pump New York dock-water into the sewers, and that it would be very injurious if it could be done. Almost all our sewers empty into the docks, and the water there is of the foulest kind. I do not believe in a long quarantine, and think that of the Dutch is the best. They only detained the sick, but took the addresses of all who were let through, or kept back all their soiled clothing, which they had washed, disinfected, and sent after their owners in three days.

St. Louis still has 20,000 privy-pits and as many surface wells. The importation of cholera into St. Louis is well proven for 1832, 1848, 1849, 1854, 1866, and 1873. Those who used surface well-water suffered much more than those who drank Mississippi water, however foul that may have been. The history of cholera in St. Louis has been better and more accurately written up quite lately by Mr. Robert Moore, civil engineer, than that of any city in this country. He has kindly given me maps of the city, with every case marked down, with street and number, for all the epidemic.

Hypodermic injections of atropine and morphine have failed sadly in many cases. Subcutaneous injections of large quantities of salt and water, with some soda, and large rectal injections of tannin and laudanum have been very successful in Italy. If there is plenty of acid gastric juice in the stomach the cholera poison and microbes may be swallowed with impunity. The worst cases of cholera are produced by drinking large quantities of cholera-contaminated water, when the stomach is empty and alkaline. I think it probable that large quantities, as much as the thirst requires, of a weak acid water will prove very beneficial in cholera. Water slightly acidulated with sulphuric, nitric, or muriatic acid will probably be the best, but it is hoped that phosphoric, acetic, and lactic acids will prove equally good. Lemon-juice and vinegar are merely acetates and citrates of potash and are not as good.

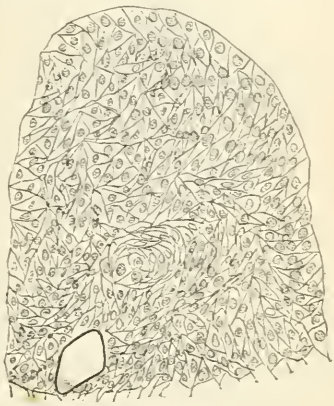
Gum Ammoniac, rubbed up with camphor, makes a mass at once suitable for pills, which are very useful in some nervous and spasmodic troubles, not only of the stomach and bowels, but also of the chest, especially when there is a too copious bronchial secretion.

THE MICROSCOPICAL EXAMINATION OF SPECIMENS REMOVED FROM GENERAL GRANT'S THROAT.

By GEORGE R. ELLIOTT, M.D.,

NEW YORK.

From numerous inquiries that have been made of me regarding my microscopic examination of the specimens removed from General Grant's throat, and from the great interest manifested in his case, I have consented to place



Epithelial Lobule showing Cell-nests.

before the medical profession the data upon which the diagnosis rested.

When the importance of using the microscope to determine the exact nature of the malady became apparent, I was invited by Dr. J. H. Douglas to assist him, and he then sent me some scrapings from the surface of the sore on the right posterior pillar of the fauces. These little particles I carefully prepared in the usual way and examined with the microscope. Little, however, of definite value could be made out, because the specimens had, unfortunately, been allowed to dry up before they came into my possession. They were consequently useless for purposes of microscopic examination.

On the morning of February 18, 1885, the importance of a further and more satisfactory investigation was sug-

Fig II

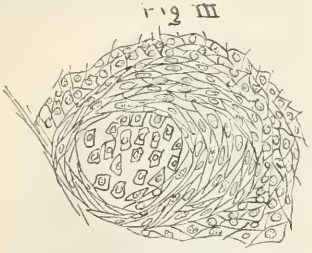
Proliferation of Epithelial Cells.

gested to General Grant, and the necessity of removing a small piece of the diseased tissue for that purpose was made known to him. Consent was readily obtained. I was then permitted to see the extent of the gross lesion, and was furnished with a history of its development.

The description given in The Medical Record on March 7, 1885, of the site and extent of the disease, corresponds with my recollections of the accounts that I

received at that time. As there stated, the area of disease was not great, and the pillars of the fauces on the right side were the parts most involved, the adjoining side of the tongue being indurated to a slight extent only.

Preliminary to cutting off any of the diseased tissue the throat was sprayed with a four per cent. solution of the hydrochlorate of cocaine, which allayed, to a great extent, the irritability of the affected tissue. A piece about



A Developing Cell-nest.

as large as a small pea was then removed by Dr. F. C. Riley, from the ulcerated edge of the posterior pillar of the fauces. The removal took but a moment, and gave the patient little discomfort. The specimen was placed at once in alcohol and water, equal parts, for the purpose of hardening it. After immersion for twenty-four hours, the specimen was transferred to absolute alcohol, in which it was kept for twenty-four hours longer, when it was found possible to make thin sections. The latter were stained, in order to bring out more clearly the minute component parts. The staining reagents used were hæmatoxylon, Bismarck brown, and hæmatoxylin and eosine. Subsequently these sections were mounted on glass slides in Canada balsam.

I found that the tissue examined was composed largely of epithelial elements, grouped frequently under the form of distinct lobules. The cells forming these lobules lay in close contact, and showed a marked tendency to be arranged in concentric globes or "nests." This latter arrangement of epithelia is characteristic of that form of cancer known as the epithelioma.

Most of the globes were found to be in an early stage of formation. I do not wish to be understood as basing my diagnosis of epithelial cancer upon these globes or

A Cell-nest showing Corneous Degeneration.

nests only, but in connection with other pathological and clinical data I regard their presence as highly significant.

Marked multiformity in the shape of the epithelial elements was another of the important findings in the specimens under examination, while distinct evidences of cell-proliferation were seen in the Malpighian layer. By the lobulated appearance of the epithelial mass referred to above is indicated a tendency of the new cell-formation to burrow into the deeper parts of the underlying tissue. Extravasations of blood were also found among the epithelia. This condition I regard as pointing to a low vitality of the newly developing growth, and cell dissolution, leading to rupture of the capillary blood-channels, by which their contents escape into the surrounding tissue.

Finally, in some parts of the diseased tissue a fibrous framework was found.

By way of summary, then, the more or less lobulated appearance of the epithelial mass; the actual existence of some "cell-nests;" the great diversity in the shape of the cell elements; the marked evidences of epithelial proliferation, and the peculiar appearance of the stroma, warrant the diagnosis of epithelioma of the squamous variety.

This conclusion has been arrived at, after the greatest possible care had been taken to exclude all possibilities of error; after an exhaustive study of every detail, with a knowledge of the clinical history of the case, and this, too, with a mind anxious only to find microscopical evidence that the disease was of a benign or innocent nature.

Since sending in my first report I have shown the specimens to Dr. T. E. Satterthwaite, the well-known pathologist, and he fully corroborates my diagnosis. I have also, upon request, shown the same specimens to Drs. Fordyce Barker and J. H. Douglas, the eminent gentlemen in charge of the case, and to Drs. Henry B. Sands and George F. Shrady, the consulting surgeons, all of whom appreciated the significance of the appearances, and expressed themselves accordingly.

In conclusion I may say that this case illustrates the peculiar value of the microscope as an aid in diagnosis, since without it a positive conclusion could not have been reached upon the exact nature of the disease. In many instances, it is true, we cannot be so positive, either because we are not fortunate enough to obtain the particular part of the diseased tissue that shows the characteristic structure upon which the diagnosis is made with the microscope, or it may be that the disease is at that early stage, when it exhibits nothing that is pathognomonic.

The great interest of this case, not only to the medical world, but to the public at large, has induced me to describe in some detail the examination of a specimen that exhibits nothing but what is constantly found in an epithelioma of ordinary type that is fully developed.

TOXIC ENTERITIS, CAUSED BY CORROSIVE SUBLIMATE AS A SURGICAL APPLICATION.[1]

BY GEORGE L. PEABODY, A.M., M.D.,

VISITING PHYSICIAN AND PATHOLOGIST TO THE NEW YORK HOSPITAL.

IN the February number of *Virchow's Archiv* an article with substantially the above heading appears, by Dr. Eugen Fränkel, prosector in Hamburg. His attention seems to have been called to the subject by a short communication in the *Centralblatt f. Gynäkologie*, by Stadfeldt, of Copenhagen, in which is reported a fatal case of poisoning in a woman who was treated for retained placenta. After manual removal, her uterus was washed out with a solution of the poison in question, of the strength of 1 to 1,500. Four hundred cubic centimetres of this solution had been injected when she suddenly suffered from collapse, from which she rallied under appropriate treatment. On the evening of the same day she had diarrhœa and tenesmus, and later bloody stools which continued until her death, ten days later. The autopsy revealed in the large intestine numerous ulcers of an irregular or circular shape. The mucous membrane was congested, generally, and the ulcers were especially frequent in the rectum.

This condition of ulceration throughout the large intestine corresponded so closely with the results which I have found in several autopsies, recently, of persons subjected to the action of bichloride of mercury, that I was tempted to search my records for facts bearing upon the question, and was quite surprised at the evidence which

[1] Read before the Practitioners' Society, on March 6, 1885.

was thus acquired. Before proceeding to narrate my own cases, however, which I shall do briefly a little later, it may be interesting to proceed further with Dr. Fränkel's paper. He goes on to quote those fatal cases, of a similar kind, published by Winter in the *Centralblatt f. Gynäkologie*, No. 43, 1884. He then says that he has made autopsies of fourteen cases, treated by Schede with this poison, in which toxic enteritis was produced by it, during the last two years and a half. Of these fourteen cases, two, he thinks, were killed by the action of the poison directly. In the others, he seems to think that the action of the drug was not *wholly* responsible for the fatal issue. These cases were of the following kinds: seven phlegmons, two caries of vertebræ, one psoas abscess, one amputation of thigh, one removal of mamma and axillary contents, one laparotomy for the removal of uterus and its appendages, one supra-hepatic echinococcus cyst, one myomotomy. This list, it will be observed, includes fifteen cases instead of fourteen.

Salivation is very exceptional in these cases of poisoning. The inflammation was always present in the large intestine, but only exceptionally in the small intestine. In the former he found often very extensive superficial ulcerations, sometimes covered with loose masses of epithelium, and sometimes by a torn diphtheritic membrane. If the patients lived long enough this membrane was cast off and deep ulcerations, often exposing the muscular coat, were apparent. Sometimes many small, round, cleanly cut ulcers were found.

With great care he proceeds to point out the differences between this form of dysentery and the lesions of these parts caused by pyæmia. Moreover, the lesions of pyæmia in the other organs of these subjects were uniformly absent. He considers the ulcerative process due to an elimination of the drug by the large intestine, and holds up to ridicule the assertion made by Bott that corrosive sublimate applied to the surface has only a local action, as proved by the absence of mercury from the urine of patients thus treated. Its absence from the urine, in these cases, proves merely that it is not thus excreted in these cases; and we should, therefore, search for mercury first in the stools, second in the saliva, and third in the urine.

To the list of cases which seem to illustrate well the danger of corrosive sublimate as a surgical antiseptic, I may add one quoted from the *Lancet* of September 16, 1881, by Wood, in his "Handbook of Therapeutics, Materia Medica, and Toxicology." In this case a solution of the strength of gr. ij. ad 3 j., was applied to the scalp of a child nine years of age, for the cure of tinea tonsurans. The symptoms following it were diarrhœa, profuse salivation, great prostration, and death.

The records of the New York Hospital for the past eighteen months, have been searched by Dr. H. W. Stevens and myself for similar cases. Accounts have been discovered of eleven cases in which the use of the poison, as an antiseptic dressing or application, was followed by obstinate diarrhœa, which did not yield to the usual remedies, and which sometimes ceased on the drug being discontinued, but which, in seven instances, was followed by frequent bloody discharges, griping, tenesmus, prostration, and death.

In three of these seven cases autopsies were made, and in each of them a very extensive diphtheritic inflammation of the large intestine was found.

The cases, briefly narrated, are as follows:

Edith S——. Necrosis of femur, with extensive sinuses and granulating surfaces. Irrigation with solution of bichloride 1 to 2,000, followed by persistent diarrhœa, which ceased on discontinuance of bichloride.

C——, an Italian, with compound fracture of femur, tibia, fibula, with much laceration. Wound irrigated with bichloride, 1 to 1,000. Four days after this treatment was begun diarrhœa commenced; soon discharges became dysenteric, with griping, and bloody stools and delirium. Amputation was resorted to, followed by death. No autopsy.

Annie M——. Large abdominal abscess. Solution of bichloride, 1 to 2,000, freely used for irrigation; followed by diarrhœa, with subsequent dysenteric discharges, and death. No autopsy.

Albert J——. Large abscess cavities and sinuses about shoulder. Irrigation with solution of bichloride, 1 to 2,000, followed by uncontrollable diarrhœa, which ceased on discontinuance of irrigation.

Bruno S——. Necrosis of pelvis; large abscess cavity. Irrigation with solution of bichloride, 1 to 2,000; uncontrollable diarrhœa, at times dysenteric. Death. Autopsy showed diphtheritic inflammation of large intestine.

James McG——. Necrosis of femur and pelvis; large cavities. Irrigation with solution of bichloride, 1 to 2,000; uncontrollable diarrhœa; at times dysenteric. Death. Autopsy showed diphtheritic inflammation of large intestine.

James O'N——. Suppurating arthritis of knee; burrowing of calf and thigh; counter-openings and irrigation with solution of bichloride, 1 to 2,000; persistent diarrhœa, ceasing on discontinuance of bichloride.

George C——. Crushed leg; very large granulating surface. Irrigated at dressings with solution of bichloride, 1 to 2,000. Persistent diarrhœa, which ceased on discontinuance of bichloride.

A. C——. Amputation of breast and removal of axillary contents. Irrigation with solution of bichloride, 1 to 2,000. Copious dysenteric discharges on third day. Death. Autopsy showed operation wound in perfect condition, and diphtheritic inflammation of large intestine.

H——. Supra-hepatic hydatid cyst. Opened; irrigated with solution of bichloride, 1 to 5,000, on fourth day. Soon after, vomiting, hiccough, diarrhœa, dysentery, with griping and bloody stools. Exhaustion, death. No autopsy. In this case the patient suffered from nausea, headache, and partial suppression of urine, before the use of the bichloride.

S——. Laparotomy for fibro-myomata. Peritoneum wiped with sponges wet with bichloride solution, 1 to 2,000. Diarrhœa, which became dysenteric, with griping and bloody discharges. Death. No autopsy.

After having written the above brief communication, my attention was called to a publication by Schede,[1] of Hamburg, on the subject of antiseptic treatment of wounds with corrosive sublimate, bearing date February, 12, 1885, and also to one of the same date by W. Thorn,[2] assistant at the Female Clinic in Halle, which is an urgent plea against its use in midwifery.

Schede admits frankly the dangers in certain conditions, and under certain circumstances; but thinks it still doubtful whether some of the intestinal lesions which have been ascribed to it, may not be due to other causes, especially to pyæmia.

Fränkel, however, carefully differentiated his cases from pyæmia, and in my own cases the usual lesions of pyæmia were absent.

Schede gives histories of several fatal cases of poisoning, with greater or less destruction of mucous membrane of the large intestine, reported by different observers in lying-in women, in which, however, other contributing causes of death are alleged. He concludes that for surgical purposes it is still the best antiseptic, if it be used discreetly, and with the full knowledge of the symptoms of its poisonous effects; but he instances several classes of cases in which even he considers it unsafe.

Thorn makes an urgent plea for its total abolition from midwifery and gynecology, alleging its great inferiority to carbolic acid, and the dangers attending its use. His paper is accompanied, as is Schede's, by elaborate statistics, which will well repay perusal.

[1] Volkmann's Sammlung klin. Vorträge, No. 251. [2] Ibid., No. 250.

It is not my purpose to do more than call attention to the facts which have come to my knowledge on this subject, and to sound a warning to those who are using the bichloride of mercury extensively in surgical, obstetrical, and gynecological work.

It seems only right to emphasize the fact that, so far as I have been able to learn, death has not resulted from its use in surgical dressings, such as bandages, etc., but only after irrigation of abscess cavities, uteri, vaginæ, large wounded surfaces, the peritoneum, etc., etc.

It is not unlikely that many deaths have resulted from its use that have been ascribed to other causes, for the reason that we have only recently become aware of the possible dangers that attend it.

Progress of Medical Science.

Infectious Pseudo-Rheumatism.—All the infectious diseases, although in varying degree of frequency, may be complicated by articular affections. These articular localizations are often mistaken for rheumatism, but ought to be clearly distinguished, since they are only the local manifestations of a general infection. In addition to these well-defined diseases there are certain other ill-understood infectious conditions which present in their course rheumatical affections, which are frequently attended with suppuration. Most of the reported cases of acute suppurative rheumatism are, according to Dr. Bourcy Paul, instances of this nature. All the forms of infectious pseudo-rheumatism, the author states, have a certain number of characters in common, which serve to establish their relationship: 1. They are met with during the course, or at the decline, of infectious states in persons absolutely free from rheumatism or any of the conditions related to it, as nephritis, asthma, etc. 2. The course of the temperature is not that of true rheumatism. 3. Albuminuria is usually present, and whenever an examination could be made, inferior organisms have been found in the urine or blood. 4. The visceral lesions (fatty degeneration of the liver or kidneys, enlarged spleen, sub-serous hemorrhages, etc.) show that the articular localizations are simply epiphenomena of a general disease. 5. These joint affections are remarkable for their gravity, for the predilection which they show for the larger articulations, and for their tendency to suppuration and rigidity. 6. All the joint tissues may be involved. 7. When suppuration occurs micro-organisms are found in the pus. 8. The action of cold appears to be only in exceptional cases the determining cause. 9. Salicylate of soda is of very little efficacy in the treatment of these joint troubles. Affection of the cardiac serous membranes may coincide with the articular disease, and is not subordinate to it, since both originate from a common cause, viz., the general infection of the organism.—*Simale Internazinale delle Scienze Mediche*, December, 1884.

Percussion of the Intestine.—Dr. P. Jashchenko writes in the *St. Petersburger Medicinische Wochenschrift*, No. 41, 1884, upon percussion of the intestines and what it teaches. He states that by means of this method of examination it is possible to determine the amount and the position of the intestinal contents, and also to follow their course from the time that they are expelled from the stomach until they enter the sigmoid flexure. The ingested food, he says, enters the small intestine in about four hours after it has been swallowed. In the evening (about ten o'clock if the individual has dined about two o'clock) it begins to pass from the small into the large intestine, and on the morning of the following day, soon after stool, it finds itself in the right half of the transverse colon. The following morning it passes into the left half, and soon after stool passes into the sigmoid flexure, where it remains until the morning next following (that of the fourth day), when it enters the rectum. In constipation the percussion-note over a greater or less extent of the large intestine becomes dull, after a three days' constipation, indeed involving almost the entire length of both the descending and transverse portions of the colon. It is thus possible often to tell with a considerable degree of accuracy the length of time that constipation has lasted, and to institute, therefore, a rational mode of treatment. By means of percussion, also, it is often shown that a diarrhœa, which has been treated by opiates and astringents, is due really to the presence of fæcal masses in the intestine. In an ordinary case of constipation Dr. Jashchenko seeks to restore normal action by regulation of the diet rather than by purgatives.

Contra-indications to Mercury in Syphilis.—At the recent meeting of the British Medical Association, A. Cooper, F.R.C.S., read a paper on syphilis. After pointing out the great value of mercury in the treatment of the disease, and the necessity for prolonged courses of the drug, he draws attention to the contra-indications, which many physicians are apt to overlook or to neglect. Mercury should not be given to phthisical subjects, unless the chest affection is slight and the patient's health is good in other respects. When albuminuria exists mercury must, of course, be withheld, unless there is reason to believe that the renal affection is due to syphilis. When syphilis exists in scrofulous subjects, if the symptoms of scrofula are not very severe, mercury may be given with care in small doses. Mercury is contra-indicated in profound anæmia, when non-specific. The least symptom of sloughing or phagedena should prevent any thought of administering mercury. If any of these complications set in during a course of the medicine, it should be at once discontinued. Alcohol and tobacco should be avoided or used sparingly during a course of mercury. Exercise and fresh air tend to prevent salivation; and the skin should be kept perfectly clean. Confinement to the house is desirable when any eruption appears.

Caffein in Heart Disease.—Professor Riegel, of Giessen, recommends caffein as a substitute for digitalis in cardiac affections. He has tried it in several cases, chiefly in the form of a double salt of soda, and has found it of great service. It regulates the heart's action, diminishing the frequency while it increases the volume of the pulse, and increases the urinary secretion. It is suitable for all cases in which digitalis is indicated, and it sometimes succeeds where the better known remedy fails. Its action is also more prompt than that of digitalis, and it has no cumulative effect. It is most efficacious when given in repeated small doses. Dr. Bechers also favors the employment of this drug. He cites some cases in Professor Nothnagel's clinic, where caffein had been employed in cardiac affections, to the amount of thirty grains *per die*. It was found to be in some cases more efficacious than digitalis, and in all cases the absence of cumulative action was very beneficial. The citrate was most frequently employed, and sometimes also the hydrobromate. Toxic effects, consisting of confusion in the head, giddiness, and vomiting, were observed in one case after the administration of two grammes a day, but larger doses were taken repeatedly without producing any disagreeable symptoms.—*Wiener Medizinische Blätter*.

Hydrobromate of Quinine.—From an experimental study concerning the pharmacological action of hydrobromate of quinine, Dr. Tumas (London *Medical Record*, December 15, 1884) draws the following conclusions: 1. Hydrobromate of quinine markedly arrests alcoholic fermentation as well as putrefaction of blood. 2. Subcutaneous or intravenous injection of small (2½ milligrammes to 1 centigramme per kilogramme of the animal's weight), middling (1 centigramme to 25 milligrammes per kilogramme), and large (3 to 5 centigrammes per kilogramme) doses is immediately followed by a decrease of the arterial tension, the fall being of various degree and duration according to the dose used. 3. Under small

and moderate doses the pulse increases in frequency, but soon returns to the standard; with large doses, it is retarded from the beginning, the retardation lasting for a prolonged period. 4. The fall of the blood-pressure is dependent upon paresis of the vaso-constricting, and stimulation of the vaso-dilating, nerve-apparatus. 5. Muriate of quinine brings about similar phenomena, but the hydrobromate acts more strongly and for a longer time than the muriate. 6. In moderate doses, hydrobromate of quinine at first slightly increases the frequency of the respiratory movements, but very soon there appears a marked decrease in the number of the latter, and in the degree of the respiratory excursions. Repeated injections of a moderate dose, or the administration of a large dose, diminish the frequency of respiration and the degree of respiratory excursions, and finally arrest respiration in the stage of expiration. 7. Hydrobromate of quinine, whatever the mode of its introduction may be, very strongly depresses the excitability of the psycho-motor centres. The period between the stimulation of the pysycho-motor centres, and the contraction of corresponding muscles becomes twice or three times longer than in the normal conditions. To bring about epileptoid convulsions after an injection of hydrobromate, a stronger electric current is required than before the injection. 8. To produce a certain fall of the blood-pressure, in an animal with "sthenic" fever, a far larger dose of hydrobromate is required than to bring about an equal fall in a healthy animal. On the contrary, in cases of "adynamic" fever, the blood-pressure falls from considerably smaller doses than in a normal animal. 9. Chronic poisoning by hydrobromate of quinine, produced in puppies by means of daily subcutaneous injections of moderate doses for a month, is manifested by loss in weight of the animal's body, general sluggishness, permanent slight decrease of the temperature, diminution of pathic and electric sensibility, and decrease of excitability of the psycho-motor centres.

Tetanoid Symptoms Occurring in Dilatation of the Stomach.—Among the numerous complications which have been attributed to dilatation of the stomach tetanoid accidents are of rare occurrence, yet have occasionally been observed. M. Laprévotte has collected several cases in which this symptom was associated with the organic affection. From a study of these cases he concludes that the convulsive attacks occur at an advanced stage of the disease. Sometimes they are of short duration and are not repeated, and at other times they are so severe and occur so frequently as to render the prognosis quite grave. The principal diagnostic difficulty lies in the fact that the gastric affection is apt to be overlooked. M. Laprévotte believes that the tetanoid convulsions, like the other nervous symptoms occurring with gastric dilatation, are due to the formation within the stomach of alkaloids of decomposition analogous to ptomaines. — *Archives Médicales Belges*, November, 1884.

Carcinoma and Syphilis.—The relations between these two affections have been studied chiefly by Verneuil, but in a recent article Dr. Ozenne treats at some length of the characteristics of this hybrid condition as it is observed in the buccal cavity. The paper has to do only with cancer as associated with the tertiary manifestations of syphilis, for hitherto the disease has not been observed in connection with the earlier syphilitic lesions. The hybrid affection is seen under three forms: the sclero-cancerous, the gummo-cancerous, and the sclero-gummo-cancerous. In the first of these forms the cancerous tumor usually appears first, though sometimes the syphilitic lesion precedes, and then suddenly we have presented a mixture of the carcinomatous neoformation with the alterations of sclerotic glossitis. The tongue is increased in volume, and at a certain point the cancerous tumor is seen as an irregular induration of variable size, either projecting above the surface if the neoplasm is superficial, or under the form of an elastic, resisting, submucous tumor, with indurated base, if the epithelioma is of the interstitial variety. Alongside of this part invaded by the cancer are seen the indurated lesions of the syphilitic affection, over which the mucous membrane appears smooth, glistening, and pale. More frequently, however, we have a dermo-parenchymatous glossitis, the induration of which, instead of being lamellated is diffuse and deep, and gives to the finger a peculiar, dry, hard feeling. In the gummo-cancerous form, the two diseases are so blended together that the characters of either are almost wholly lost. There is a deep ulcer, the base of which is indurated as in cancer, but whose edges are not sharply cut, and it does not bleed as does the cancerous ulceration. The third form is still more complex. Gumma, carcinoma, and dermo-parenchymatous sclerosis are associated together in variable proportions, sometimes one or the other being the most distinct, and sometimes all being blended together in indistinguishable confusion. As regards the functional symptoms of this hybrid affection, they are less severe usually that when either one of the lesions occurs separately. Thus hemorrhage is rarely seen, and the pain which accompanies cancer is often wanting. The prognosis, however, is, unfortunately, always that of carcinoma. Yet treatment with the iodides should be tried whenever it seems probable that a syphilitic lesion is engrafted upon the cancerous one, but mercury exerts a most injurious effect upon cancer of the mouth, and should therefore never be exhibited.—*Archives Médicales Belges*, November, 1884.

The Etiology of Progressive Ossifying Myositis.—We have received a reprint from the *Zeitschrift für klinische Medicin* containing a report of several cases of this affection by Dr. Gyula Pintér. The author excludes heredity and traumatism as etiological factors, but believes that there exists a congenital predisposition in the subjects of this disease. His grounds for this opinion are as follows: 1. He was unable in the cases collected or observed by him to discover any cause—either traumatism or unfavorable hygienic surroundings—to which the origin of the affection could be referred. 2. In almost all the cases the disease made its appearance in early childhood. 3. In a series of cases in which the disease appeared at a later period it was always preceded by a peculiar symptom, viz., a growth of nodules or boils in the scalp, which disappeared after some months, leaving no traces of their presence. This symptom was noticed either shortly after birth or at a period preceding by some years the commencement of the ossifying myositis. 4. Finally, in a large proportion of the cases there was a congenital microdactylus, and such a peculiar deformity occurring with such frequency would seem certainly to point to some congenital predisposition. The author does not venture an opinion as to the nature of the embryonal predisposition, but remarks upon the fact that the only muscles which were never involved in the ossifying process were those formed from the parietal zone of the inner group of embryonal elements, while those derived from the parietal zone of the external blastodermic membrane and from the intermediate layer were sometimes affected and sometimes free. The proportion of males to females suffering from the disease was as two and one-half to one, but the females seemed to be affected in greater degree than the males. Eighteen of the twenty-two cases collected were reported in Germany, England, and America. The author asks whether the fact that the disease occurred with greatest frequency in the bony German and Anglo-Saxon races is merely a coincidence, or whether it is of some etiological importance, but he leaves the question unanswered.

Nitrite of Amyl is well given in sweet spirits of nitre, which is also useful in arterial spasm and in the heart-pangs of angina pectoris.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 14, 1885.

NATIONAL HEALTH LEGISLATION.

CONGRESS has adjourned, and we can now estimate the character of the legislation relating to questions of medical interest. And, first, we notice the fact that the National Board of Health has not only obtained an appropriation covering deficiencies, but a fund has been supplied it for the coming year. Considering the persistent and unscrupulous efforts of certain officials of the Treasury Department to destroy the Board, and obtain control of the funds appropriated for the prevention of epidemics, the action of Congress is eminently satisfactory, and insures the permanency of a competent national health authority. Fortunately for the public health interests of the country, the official of the Treasury Department who organized and promoted the schemes for the injury and final destruction of the Board was promptly dismissed by the new Administration, and it is to be hoped that all the evil influences which he created will follow him into obscurity. But for this single individual, who was so placed as to be able to prejudice the minds of Congressmen, and divert the appropriations for the public health into other channels, we are convinced that the National Board of Health would always have been as popular with Congress, as with the public at large.

The fund appropriated to be used at the discretion of the President, in case of a threatened or actual epidemic of cholera or yellow fever, amounts to about $340,000. A clause ingenuously inserted in the Sundry Civil Service Bill, requiring that the President shall expend this fund *through the Marine Hospital Service*, was stricken out. The President is, therefore, left to select, at his discretion, the method of making the best possible use of the fund at his disposal to prevent the introduction of cholera into this country, and to aid local boards. There is no doubt that he will select the National Board of Health, and that this body will immediately meet and mature plans for the prevention of cholera. We have already stated, in outline, the measures which we have reason to believe, from its published reports, that Board would adopt, and we wish to reiterate the statement that no time should now be lost in perfecting the necessary machinery, and setting it in operation. As we view the matter, it will prove no slight task to organize the proper maritime and coast defences, and successfully administer the details of work. Health officers of ports, State boards of health, and the Canadian health authorities should meet the National Board in conference, and agree upon common methods of defence, with a view to co-operation and concert of action.

A weekly bulletin of the public health of cities, foreign and domestic, with the progress of contagious and infectious diseases, should be issued at once for the information of health officials.

To accomplish these results time will be required—which is now precious—if we hope for successful results. We trust the President will not delay action, but will at once call the National Board to his assistance, and empower it to act promptly and decisively in this great emergency.

The appropriation to erect a building for the museum and library of the Surgeon-General's office was passed, and we are, therefore, to have a building on the grounds of the Smithsonian Institution worthy of the object for which it is created.

The bill to purchase the Seamen's Retreat, Staten Island, for the use of the Marine Hospital Service, failed to pass. It proved to be a piece of jobbery of no small dimensions. An appropriation of $7,000, to enable the Supervising Surgeon-General of the Marine Hospital Service to go abroad, and study hospital construction, was very properly defeated. We shall take occasion hereafter to show that the whole system of establishing hospitals for sailors ought to be abolished.

THE MEDICAL VIEW OF ROLLER-SKATING.

IT seems as if America were peculiarly susceptible to epidemic influences of a mental kind. We hear of no other country so violently perturbed by "waves" of temperance crusading, religious revivals, velocipede crazes, pedestrianism, and, finally, roller-skating, upon which latter pastime the thoughts and feelings of three-fourths of the rising generation are at present centred. In intensity and extent, the roller-skating mania has far exceeded all its predecessors, and it must be inferred, either that the psychological contagium is particularly strong, or that the susceptibility of young America to affective epidemic influences is increasing.

Modern scientists of the "Psychical Research" school are putting forward the theory of brain-waves as a possibly potent element in the production of panic fears and epidemic fashions and feelings. The mind acts "exoneurally," we are told, and the vibrating brain-cells of the enthusiastic roller-skater communicate their rhythmical pulsations to the previously insensitive spectator. Whatever the mechanism, there is certainly at present a morbidly exaggerated passion for, and indulgence in, roller-skating. And the question comes home to the physician, whether it is doing any physical or mental harm.

On the whole, we are inclined to take a rather lenient view of the present craze. Considerable inquiry has failed to elicit any facts showing that roller-skating, temperately indulged in, does any harm to growing children, or produces any diseases and injuries peculiar to the sport. Severe sicknesses have been known to result from violent exercise in hot, ill-ventilated rinks, and occasionally serious injuries are produced by falls and collisions. In proportion to the immense number of persons who have been engaged in propulsive divagations upon polished floors during the past winter, the pathological outcome has been small.

GENERAL GRANT'S CONDITION.

Since the last bulletin of The Medical Record was issued a consultation has been held on General Grant's case, attended by Drs. Fordyce Barker, J. H. Douglas, Henry B. Sands, and George F. Shrady. At that time, Sunday, March 8th, the general condition of the distinguished patient was quite feeble, although he was able to walk across his library and seat himself in the chair for the necessary examination of his throat. The latter was possible without giving him pain. It was found that the ulceration of the posterior pillar of the right fauces had extended and that the perforation at the base of the anterior pillar had increased, so that its internal edge was converted into a small bridle of tissue. The entire soft palate was uniformly reddened and swollen, and the right posterior border of the tongue was indurated from a point just in front of the anterior pillar of the fauces as far back as could be reached by the finger. The gland under the right angle of the jaw was still enlarged and hard, but quite movable.

The pain in the ear had entirely disappeared and there was no special difficulty in swallowing, neither was there any marked salivation. The most grateful local application to the throat next to the spray of a four per cent. solution of cocaine was that of a hot solution of salt and water, in the proportion of five parts to the thousand, used occasionally as a gargle.

The patient complained that his sleep was irregular and fitful and that he was thereby converting night into day. Codeine in grain doses was accordingly recommended as the anodyne, otherwise no change in the general treatment was suggested. The local applications employed by Dr. Douglas were fully indorsed. The previous diagnosis of the disease of the throat was unanimously confirmed.

The administration of the anodyne was subsequently attended with the good result of securing five hours of uninterrupted slumber at a time. In the course of the following three days the effect was not so marked, and another sedative was prescribed.

The angry redness of the palatal curtain has in a measure disappeared, and there is now occupying a considerable portion of its left side a triangular-shaped, sharply defined granular exuberance which has an ominous appearance.

The ulcerative process in the anterior pillar has, since the consultation, extended to the adjoining side of the tongue, and the bridle of tissue bounding the perforation of the anterior pillar internally gave way on Wednesday. During Thursday the patient was in a reasonably comfortable state; his temperature was normal and his pulse regular, but he was suffering somewhat from the effects of insomnia. His digestion is good, and semi-solid food is taken easily and with a reasonable relish. He suffers no pain. In the face of all these general symptoms the local difficulty has markedly increased, and the parts in the vicinity of the ulcerations are becoming more infiltrated.

THE DIFFICULTIES OF MEDICAL LEGISLATION.

The medical profession in several States of the Union are in the throes of prospective legal regulation. The matter is being particularly agitated in Kansas, Texas, and Ohio, as well as in New York. The bills prepared for passage in these States do not any of them appear to be above just criticism, and we must urge upon the State Societies that they go very slowly in pressing them.

Aside from the problem in legislation of how to treat those already in practice, the two points which involve the greatest doubt and excite the greatest controversy are those regarding the legal recognition of eclectics and homœopaths, and of a licensing board separate from the schools. Medical opinion is now practically unanimous upon the latter point. There should be a separate licensing board. As to the recognition of special schools, much difference still exists even among the wisest. In many States the profession must either allow this recognition or postpone any attempt at regulating medical practice for a long time. It is a question for each State to decide. The regular profession, those who practise rational medicine, should be extremely careful in making such concessions to special schools as would give them a fixed and legal status. Their strength is often exaggerated, and in any event it is the strength that comes from assurance more than justice. In many cases it may be possible to pass a law which will concede enough without giving any formal legal recognition of the existence of "schools," of any kind. In these days it is an anachronism that there should be dogmatic schools of medical theory and practice. We want no legal recognition of "allopathics," or "regulars," or homœopaths, but only a recognition of educated physicians.

A SIMPLE METHOD OF TESTING THE QUALITY OF HUMAN MILK.

Undoubtedly the best way to test the quality of milk is to have a thorough examination of it made by a competent chemist. As this is generally too expensive and elaborate a procedure, we have various makeshifts in the way of lactometers, cremometers, lactoscopes, etc. All these necessitate expenditure of money and time without a corresponding return in practical results. So true is this, that Professor Tarnier recommends for testing the quality of milk as primitive a method as the following: Take a little milk in a spoon or glaas, put a drop on the nail, and judge by its transparency and the way in which it flows, whether it is rich or poor in nutritive elements.

Dr. Paul Helot, Surgeon-in-Chief to the Maternity Hospital at Rouen, has suggested another method almost as simple and much more precise. Taking advantage of the fact that the size of the drops of different liquids differs according to their density or molecular cohesion, he determined the average number of drops in a certain volume of healthy human milk at a temperature of about 15° C. (60° F.). The same was done for distilled water. He used for the purpose a Pravaz syringe, holding one cubic centimetre without the needles. It was found that one cubic centimetre of good human milk gave thirty-five drops from the syringe; the same volume of water gave thirty drops. Hence the formula: In a dropper of a given capacity the number of drops of distilled water at 15° C. is to that of woman's milk as six is to seven. Some variations occur within healthy limits; if, however, the number of drops was below thirty-three or above

thirty-nine or forty, the milk should be rejected. As human milk varies at different times, the standard adopted was that of a healthy mother nursing a healthy two months' child, samples of milk being taken from each breast at the mid-period of nursing.

Doubtless Dr. Helot's method will prove a useful one when a physician is called upon to judge of the quality of the milk of a wet-nurse or a mother. It is at least easily tried, and involves no apparatus but a hypodermic syringe.

A NEW METHOD, BY WHICH ONE CAN SEE THE SHADOWS OF ONE'S OWN RETINAL VESSELS AND YELLOW SPOT.

THE visual sense is perhaps the most completely specialized, as it is the most delicate and complex of all the functions of the body. An enormous amount of patient labor and minute investigation has been expended upon its elucidation. Some of these investigations are not unattended with danger, as for example, the prolonged study of the retinal after-images, in which one celebrated physiologist almost lost his vision. One of the most curious lines of investigation has been that of the self-study of the retina. Purkinje was, we believe, the first to describe a method by which the shadows of the retinal vessels and yellow spot could be seen. This method is as follows: While looking at a dark ground in a dark room, one concentrates with a lens the rays of light from a gas jet, and throws them obliquely on the sclerotic immediately behind the sclero-corneal junction, or on the cornea itself. On rapidly moving the lens up and down or from side to side, one then sees projected on the dark wall the image of the retinal vessels.

Dr. W. Odillo Maher, of Sydney, has published in the *Australasian Medical Gazette*, of November, 1884, a new method by which the same object is accomplished, as he believes, more perfectly.

Standing at a short distance (ten or twenty feet) from a lighted gas-jet in a dark room, and covering one eye, say the left, with the left hand, the observer takes between the forefinger and thumb of the right a strong convex lens, and holds it at about its focal distance in front of the right eye. Then, steadily gazing at the light through the centre of the lens, he shakes the lens rapidly backward and forward along its axis, or up and down, or from side to side. After a few seconds the shadow of the fovea centralis appears in the axis of vision as a light yellow patch studded with dark coarse granules. Simultaneously the retinal vessels in the region of the yellow spot, including the finest capillaries, appear as dark cords against the yellow light. This appearance, according to Dr. Maher, is not unlike Plate 72 in the last edition of Nettleship's book on "Diseases of the Eye," except that the difference between the arteries and veins is not so marked, and that one gets a more extensive view, seeing the shadow of the retinal vessels as far as the optic disk. The outline of the shadow of the fovea centralis, which falls upon the most sensitive part of the retina, the yellow spot, is well defined, while the outline of the shadow of the optic disk cannot be distinctly seen, as it falls upon a much less sensitive part of the fundus. The shorter and more rapid the movements of the lens, the sooner the shadows of the retinal vessels and fovea centralis appear, and the more distinctly are they seen.

Dr. Maher claims that this is a simple and easy way of demonstrating:

First.—That there are no blood-vessels in the fovea centralis.

Second.—That the structures in which the visual impulses originate must be behind the retinal vessels.

Third.—That the fovea centralis differs in structure from the other parts of the retina.

THE FUTURE TRIUMPHS OF MEDICAL ART.

WE can recall the time when the public press would no sooner have ventured to discuss the problems of sanitary science than those of the pathology of lupus Now the daily papers have become most apt upon these matters, and are almost taking sanitary subjects away from the domain of technical journals. It is a sign of the times which is most encouraging. We may predict, however, that in the future, as this tendency continues, preventive medicine will eventually pass from the hands of the individual physician and be placed with a separate class of special workers and State officials. The triumphs of the medical art of the future have often been rhetorically described as lying in the prevention, not in the cure, of disease. This cannot be strictly the case, since the doctor's work will become more and more limited to patching up the remnants which sanitary art and State care fail to keep whole. The steady decline in the mortality-rate in England, for example, is due more to governmental sanitary organization than to the work of the practising physicians. The doctor by individual advice will always do something to prevent disease, but his main office must ever be that expressed in the motto: "Guérir quelquefois, soulager souvent, consoler toujours."

THE ALLEGED INCREASE OF CANCER.

THERE has been considerable discussion in the past few years regarding the increase in the annual deaths from cancer. The figures of the Registrar-General's report, the writings of Dr. Charles Moore and of Mr. Dunn, have especially drawn attention to this question.

The deaths from cancer in England and Wales in the ten years 1860–69 were 80,049, with an average annual increase of 248. In the next decade, 1870–79, the number of deaths was 111,300, with an annual increase of 320. The total increase in deaths from cancer in the decade 1850–59 was 2,000; in the decade 1860–69 it was 2,400; and in the decade 1870–79 it was 3,200.

In 1874 Dr. Farr remarked that, in England, "cancer, one of the largest and most painful diseases to which mankind is subject, is growing more fatal." The rate of deaths from this disease in that country, from 1873 to 1874, was equal to 443 in every 1,000,000 of population.

In this country the vital statistics of this city show that the number of deaths from cancer in 1869 was 304, in 1875 was 415, and in 1883 was 678. The estimate was made ten years ago by our City Board of Health that the rate of deaths from cancer was but little over four hundred per million inhabitants. According to the last reports it is about five hundred and thirty per million. These figures, however, include a large hospital mor-

tality. In Brooklyn the deaths from cancer in 1883 were only 262 in a population of 624,118, which gives about the same rate as that of New York ten years ago.

It cannot be denied, in the face of statistics like the above, that the death-rate from cancer is increasing absolutely and relatively in some parts of the world.

But that there is now a greater susceptibility to cancer than formerly has not yet been proved. Cancer is a disease of the degenerative period of life. It occurs between the ages of forty and sixty. Now, improved modes of living have increased the number of persons who reach these ages. In England and Wales, for example, during the years 1838–54, out of 1,000 children born, only 309 reached the age of sixty-five; during a subsequent period—1876 to 1880—out of 1,000 children born, 333.4 reached the age of sixty-five, being an increase of nearly one-tenth. Investigations thus carried out would show, perhaps, that the number of persons reaching the age susceptible to cancer has increased in a greater ratio than have deaths from the disease. The volley from the enemy is the same, but the number brought to the front is greater.

A NEW "HABIT."

In the *Detroit Lancet* for December, 1884, the distinguished editor and Dr. J. E. Clark contribute articles upon the subject of the chloroform habit. According to the latter writer the habitual use of chloroform as an intoxicant, hypnotic, and anodyne is becoming more and more extensive, and, octopus-like, "is slowly but surely fixing its tentacles on modern society." Dr. Clark adds "that such a habit is becoming prevalent is scarcely known outside of the profession and the life-insurance companies." We might supplement this by saying that the existence of such a habit is probably unknown to most medical men, and we regret that some facts were not given that would establish solidly Dr. Clark's rather loose assertions. He himself reports five cases coming in his own personal experience, and states that in Detroit there have been three deaths as the direct result of this habit in the past eighteen months.

Of Dr. Clark's cases three were women, one of whom contracted the habit in consequence of its use to relieve toothache; a second acquired it directly as the result of the prescription of a physician, her husband, to allay headache; a third contracted its use, after parturition, to relieve dysmenorrhœa. The following case illustrates the results of the habit: "A drug clerk; addicted to the practice for over eight years; bodily and mental faculties all affected; indecision; wakefulness; nervous tremors; loss of appetite; indisposition to exertion, either mental or physical; irritable stomach; nausea and vomiting; an uneasy feeling in the precordial region, with an increasing desire for the cause of his troubles."

Another patient took about half a pint daily by inhalation. The practice usually begins by the individual inhaling a drachm or two from a handkerchief to relieve a pain or procure sleep. This dose causes no unpleasant after-effects at first, and it is continued. In course of time, however, the dose has to be increased, a craving for the drug is felt whenever there is any indisposition; dyspeptic symptoms, mental and physical debility result.

Dr. Leartus Connor contributes an interesting and graphic account of the chloroform habit as described by one of its victims. This latter tells the story of the way in which the habit was formed;

"I was a young man, just finishing my education, fond of study, and taking a keen interest in everything about me. I had had some curiosity to know what it was like to be put to sleep with chloroform, and one night, just before retiring, I happened to see a one-ounce bottle of chloroform, which had been bought to use for a toothache, I believe. I took the bottle home with me, and when I went to bed put a little of the chloroform on a handkerchief, and for the first time felt the delightful sensation of being wafted through an enchanted land into Nirvana."

He kept up the practice of inhaling chloroform every night for two years, still performing his daily duties. By the end of that time, however, he had become a slave. He as yet used only about three drachms, but after an ineffectual effort to break off, he changed his mode of indulgence, and every few weeks would go upon chloroform "sprees," when he would consume from four to eight ounces of the drug.

He at last was barely rescued from death by a physician, who subsequently attended him and cured him of his habit. The patient pays a tribute to his professional attendant, which we take pleasure in quoting:

"At last discovery came. You well remember how I was found apparently lifeless, and how by the active use of restoratives, you brought me to myself. How my moral perceptions were quickened the moment I saw myself through the eyes of another! You were a true friend to me in that hour of my trouble. I had thought the doctors only mercenary creatures like the rest of us; perhaps the majority of them are so, but when you came to me in my humiliation, and tenderly, and without word of reproach, helped me to recover my self-respect and my power of will, I gained a new idea of what the true physician may be, and sometimes is, for the sick."

Whether or not the chloroform habit is at all an extensive or growing one facts do not yet enable us to say. Physicians occasionally learn of cases, and it is well known that it is a habit easily acquired, and that it is in its beginning a most insidious and seductive one, being for some time attended with no disagreeable after effects.

Free Beds for Sick Saleswomen.—We are glad to notice that the movement in aid of saleswomen has taken the shape of an effort to secure free beds for them in a hospital, rather than in trying to establish a new hospital. The announcement is made: "The Saleswoman's Fair, which is to be held in the Metropolitan Opera House, will be opened Monday, April 20th, and continue about ten days. Its proceeds will be used for the establishment of free beds in one of the best hospitals for the use of sick saleswomen."

Alcohol in the Treatment of Insanity.—Dr. W. B. Fletcher, Superintendent of the Indiana Hospital for the Insane, and Dr. R. M. Bucke, of the London, Ontario, Asylum, have entirely abandoned the use of alcohol in any form in the treatment of the insane. They believe that their patients do just as well as before, and perhaps better.

News of the Week.

Cholera has broken out at Java.

Small-pox has appeared at Syracuse, N. Y.

Dr. Edward S. Peck has been appointed ophthalmic surgeon to the St. Elizabeth's Hospital, New York City.

The American Veterinary College held its annual commencement March 4th, graduating a class of twenty-eight.

The Minnesota Hospital College held its fourth annual commencement on February 27th, graduating a class of sixteen.

The Nebraska State Medical Society will hold its seventeenth annual session at Grand Island, Neb., Tuesday, May 26, 1885.

Miquel's Experiments appear to show that the number of microbes in the air is always proportionate to the density of population.

The Woman's Medical College of Philadelphia held its annual commencement on March 11th, graduating a class of twenty-two.

The Louisiana State Medical Society meets at New Orleans on April 21st. The American Medical Association meets the following week.

Paris as a Medical Centre Again.—In 1876 the number of medical students matriculated in Paris was 1,924; in 1883–84 the number was 5,386.

The Longest Compulsory Medical Course.—According to *The Medical Counsellor*, the Boston University School of Medicine (homœopathic) now requires of its students four annual courses of eight months each.

Civil Service Examinations in Brooklyn.—Dr. Robert L. Dickinson, of Brooklyn, outstripped sixteen competitors in a civil service examination for the vacant position of police surgeon, and received his appointment last week.

No Marine Hospital for New York.—Congress has failed to appropriate money for the purchase of the Seamen's Retreat, at Stapleton, S. I., for use as a Marine Hospital.

Dr. Nathaniel Ford, one of the oldest physicians of Brooklyn, and the *doyen* of the Kings County Medical Society, died on March 9th, in the seventy-third year of his age. Dr. Ford graduated from Bowdoin Medical College in 1836.

Failure of Homœopathy at Ann Arbor.—The classes of the homœopathic students at the Ann Arbor Medical School have fallen from eighty-eight in 1880–81 to thirty-four in 1884–85. It is admitted that the school is in a bad way.

Medical Legislation in Massachusetts.—It is reported that a committee, of which Dr. Henry O. Marcy is chairman, has prepared a bill for submission to the proper legislative committee, establishing a Board of Medical Examiners in the State of Massachusetts.

Bellevue Hospital Medical College held its twenty-fourth annual commencement on March 9th, graduating a class of 134. The address was made by Mr. Andrew Carnegie, who congratulated the class on being poor, and hence under the necessity to work. Medicine he believed was the most progressive and broadest of the professions. A short address was delivered by Hon. William H. Dorsheimer.

Albany Medical College held its fifty-third annual commencement on March 4th, graduating thirty-three students. The Alumni Association celebrated its anniversary on the same day. An address was delivered by the president, Dr. Horace T. Hanks, and Professor William H. Thomson delivered the first alumni lecture on "The Germ Theory of Disease."

Pneumonia and the Weather.—The Committee on Hygiene of the County Medical Society, one year ago, set on foot a collective investigation regarding the relations of lobar pneumonia and bronchial catarrh to the weather. Already there has been a good response. A report will be made in April or May, and gentlemen are requested to send in their cards at once.

Sleeping with Closed Windows.—The editor of the *Medical and Surgical Reporter* portrays the dangers of night air, and counsels against sleeping with open windows. Evidently our contemporary did not get his education in New York, and have to sleep in a ten by four hall-bedroom of a city boarding-house. The night air may be a poison to a few, but the average healthy man had better inhale it than take his chances with sewer-gas, carbonic oxide, and the organic matter of the breath.

Good Commencement Advice.—The New York College of Dentistry graduated twenty-four students at its commencement on March 9th. Dr. J. Smith Dodge, Jr., gave the class some advice which has a very wide application. In pointing out the road of success he warned them against the too free use of the buccinator—sometimes called the "Great American"—muscle; told them to spare their patients from the fumes of whisky or tobacco, and cautioned them not to be off fishing when they were wanted. Dr. Dodge gave the graduates three strands to weave in the rope of prosperity—mastery of their art, the character and bearing of a gentleman, and common sense.

The Marine Hospital Service and Dr. Bell.—It is stated in a Washington paper that Dr. A. N. Bell, of New York, Editor of *The Sanitarian*, is a candidate for the position of Supervising Surgeon-General of the Marine Hospital Service. Thi sappointment would be eminently fitting. Dr. Bell, as a Surgeon of the Navy, has had a service among sailors in every climate of the globe, and has studied the hygiene of ships under every varying condition which can occur. He is also personally and practically familiar with the care and treatment of the great epidemic diseases, cholera and yellow fever, and as a former Quarantine Commissioner of the Port of New York he has a large experience in this branch of preventive medicine. His appointment will, we have reason to know, give great satisfaction to the sanitarians, as well as to the medical profession throughout the country.

THE DIVISIONS OF HOMŒOPATHY.—Judging from expressions in the various homœopathic journals, the homœopaths of the country are more or less strictly divided into three sects. One represents uncompromising Hahnemannism, and its special organization is the International Hahnemannian Association; the second is homœopathy tinctured with rational medicine, and is represented by the American Institute of Homœopathy; the third class includes the so-called "liberals," who believe in the value and soundness of certain homœopathic principles and artistic methods, but who repudiate dogmatic medicine, and advocate giving up the title "homœopath."

RECENT STUDIES OF MICRO-ORGANISMS.—M. A. Béchamp has read a paper before the Academy of Sciences, Paris, on the origin of the microzymes and of the vibriones everywhere present in the atmosphere, in connection with M. Duclaux's recent communication. Béchamp argues against Pasteur that these germs are not to be sought originally in the air, where they are disseminated by the winds, but in the ground and water, where they are deposited by the disintegration of the neozoic and paleozoic rocks, and by decomposing animal and vegetable matter of all sorts. He holds this not as a mere hypothesis, but as a conclusion actually determined by his own researches.

THE SANITARY COUNCIL of the Mississippi Valley met at New Orleans during the past week. Dr. Kedzee, of Michigan, chairman of the special committee appointed to suggest a plan of co-operation between the States of the Valley to prevent the introduction of cholera, yellow fever, and other epidemic diseases, submitted a report, which was adopted. The report recommends that special sanitary regulations, such as an inspection service on lines of travel, a thorough cleaning up of cities and towns, the distribution of sanitary information, etc., be adopted by the State boards of health. A resolution was adopted asking the boards of health represented in the council to suggest the manner in which they think the money appropriated by Congress ($340,000), to be used at the discretion of the President, should be applied.

DEATH OF PROF. ELLERSLIE WALLACE.—We regret to learn that Dr. Ellerslie Wallace, who, up to two years ago, was Professor of Obstetrics in Jefferson Medical College, died on March 9th, after a long and painful illness. Dr. Wallace was born in Philadelphia, June 15, 1819. He claimed to be a direct descendant of Robert Bruce. Early in life he was a surveyor, but he afterward studied medicine under his brother, who was Demonstrator of Anatomy at the Jefferson Medical College. Dr. Wallace graduated from that college in 1843. After practising in Philadelphia and gaining a wide reputation for his skill, he succeeded his brother in Jefferson College. He afterward resigned this position to take the chair of Obstetrics. Failing health compelled him to resign his professorship about two years ago. Dr. Wallace was for two months Dean of the College, succeeding Prof. Gross.

COMMENCEMENT OF THE UNIVERSITY MEDICAL COLLEGE.—The medical department of the University of New York held its forty-fourth annual commencement on Tuesday, March 10th, graduating a class numbering 168. The address to the class was delivered by Dr. John Hall, who advised the young men to be at pains to stand well with their own profession. According to his observation the man who did not earn the good opinions of his own order did not enjoy a long success. He further advised his hearers not to confine their reading to their own exclusive line. They should widen their minds by looking into other departments of thought and inquiry. They should, moreover, strive to be educated leaders in towns and villages, where the diagnosis of sanitary troubles and the prognosis of epidemics might make a modest man a public benefactor. The following prizes were awarded: Mott gold medal to W. B. Waterman, for the best anatomical preparation; the Mott bronze medal to G. K. Meynen, for best report of surgical clinic; prize of hospital appointment for best general examination for the degree, James Clifton Edgar, Ph.B.; for competitive prize examination—first prize of $250, R. H. Wylie; second prize, of a hospital appointment, A. W. Berle: third prize, $150, E. F. Arnold; fourth prize, $100, F. A. Rand; fifth prize, hospital appointment, C. H. Gardner; sixth prize, hospital appointment, J. C. Clark.

THE TURPENTINE "THERAPEUTIC DELUSIONS."—Some time ago we published editorially a correspondent's enumeration of certain therapeutical delusions. Considerable comment was excited by the somewhat iconoclastic position taken. *The Medical Press and Circular* has recently discussed the subject in an able manner, and has in some way discovered that our correspondent is a Dr. "Iliff," a name which we hear for the first time. The only one of this correspondent's statements which is seriously criticised is that regarding turpentine. The idea that turpentine is a stimulant, according to this "Dr. Iliff," is a delusion. His opinion is at least based on some authority. For example, Rossbach, as the result of a careful study, comes to the conclusion that oil of turpentine, "if administered in a painless manner and deprived of its odor, does not cause any irritation, but rather a paralysis of the nervous centres." Administered to men it produces headache, vertigo, weariness, and sleepiness. Purkinje could hardly keep awake after taking a dose of four grammes. In all animals experimented upon, turpentine affected the heart's action very little if at all, and it invariably lowered the blood-pressure. Copeland, in fever patients, found a diminution in pulse-rate. Mitscherlich found that in men, doses of one to two grammes produced only a very slight acceleration. The conclusion is, that oil of turpentine lowers the irritability of the nervous system, and diminishes respiration, circulation, and temperature. Clinical experience in the treatment of neuralgias and other neuroses confirms this view.

DOCTORS' SIGNS IN AUSTRIA.—Austrian physicians do not generally seem to be affected with the extreme degree of modesty that is shown by the New York doctors in their signs; in the cities they are of moderate size, but in the country districts occasionally rise to alarming proportions. Once this summer I saw one in the village of St. Gilgan, in the Salzkammergut, that extended a length of fourteen paces, and was equally broad in proportion, almost covering one side of the house of its owner.—*Cor. Maryland Medical Journal.*

Obituary.

LOUIS BOPP, M.D.,

NEW YORK.

Dr. Louis Bopp died of pneumonia after a short illness, February 22, 1885. Dr. Bopp was born in Landau, Bavaria, in 1840, and received a liberal education in his native place. He studied medicine at the universities of Freiburg, Munich, and Wurzburg, and obtained his degree in 1864. He subsequently entered an asylum for the insane as junior physician, and also served a brief period as assistant surgeon in the Bavarian army during the Austro-Prussian war of 1866.

In 1867 Dr. Bopp came to the United States, settled in New York City, and began the active practice of medicine. He was a well-informed, careful, and progressive practitioner, who readily obtained and retained the confidence of his patients and met with signal success throughout his practice. He was attending physician for diseases of women at the German Dispensary for over fifteen years, and visiting gynecologist to the German Hospital; and one of the first in this city to perform the operation for the entire removal of the uterus per vaginam.

Personally Dr. Bopp was amiable, modest, and strictly honorable. He was as much esteemed by his patients as he was respected by a large circle of professional friends. He leaves a widow and two children.

Reviews and Notices.

The Human Body and its Health. By Wm. T. Smith, M.D. 12mo, pp. 203. New York and Chicago: Ivison, Blakeman, Taylor & Co. 1884.

This is an excellent little book for use in common schools, either as a text-book for pupils, or as a guide for the teacher in oral instruction. It contains the elements of anatomy, physiology, and hygiene, and at the end of each chapter are questions for specification and review. Special attention is paid to the effects of alcohol and narcotics, particularly the former, on the various parts of the human system; and though the deleterious effects of stimulants are rather overdrawn, still this is a fault in the right direction for impressing the youthful mind. The glossary at the end of the book is a useful addition. It is clearly printed in large type on good paper, and altogether is a most creditable little work.

Topographical Anatomy of the Brain. By J. C. Dalton, M.D., Professor Emeritus of Physiology in the College of Physicians and Surgeons, New York. 4to, 3 vols. Pp. 175. Philadelphia: Lea Brothers & Co. 1885.

It is a matter for great congratulation that some men can be found with qualifications and opportunities requisite for such a work as the one before us. The name of the author is a guarantee for the gratifying results of such labors.

The three beautifully printed quartos contain respectively ten magnificently executed heliotype plates, natural size, of ten longitudinal sections, fifteen horizontal sections, and twenty-three vertical sections of the brain. Each of these is faced by a diagrammatic representation of equal dimensions, tending to accentuate the important sulci, convolutions, and lobes brought out in the plates. Each representation has a descriptive page or two of explanation, bringing out the anatomical points shown. It is difficult to give an idea of the excellence and accuracy, in detail, of these plates—in fact there is no room for imagination as to how they could better or more satisfactorily represent what the author intends to convey of the topographical anatomy of this complex organ.

There is no question of the importance of the study from the points of view of the author. Anatomically and physiologically, the brain deservedly is a much studied organ. Its complexity of structure, its peculiar relation of parts, and the significance of different regions, must naturally direct attention to every renewed effort toward studying the brain topographically, and the means to that end adopted by the distinguished author seem scarcely susceptible of improvement. His methods of brain-section leave nothing to be desired in careful detail or satisfaction in results.

The series of plates represent successive sections of the entire brain, vertical, longitudinal, and horizontal, in such proximity to each other, that the continuity of the parts may be recognized and their variations of structure followed from point to point in different regions.

The work, as a whole, is a treasure for any library, and in its scope of observation and originality of design is an uniquely valuable contribution to literature.

The Sabbath for Man: A Study of the Origin, Obligation, History, Advantages, and Present State of Sabbath Observance, with Special Reference to the Rights of Workingmen. By Rev. Wilbur F. Crafts, A.M. Pp. 633. New York: Funk & Wagnalls. 1885.

Into these pages are condensed the results of correspondence by the author with over two hundred leading men all over the world, and representing every profession and industry, regarding Sabbath observance. His own views are the essentially orthodox ones, forcibly stated, yet free from the prejudice of the bigot and the hasty, illogical conclusions of the shallow thinker. He is an optimist, believing that, taking the whole world over, the sum total of Sabbath observance is greater than ever before. He regards the sanctity of the holy day as in danger from legislative action, judicial misinterpretation of law, irregular and spasmodic enforcement of existing statutes, and from "our national habit of treating the laws as a bill of fare from which each can take what he pleases." Under the topic, "Are Sabbath Laws consistent with Liberty?" he shows the distinction between the civil and religious aspects of the question, and points out how our law-making bodies rightly may, and how they do, regulate those phases of religious conviction which have to do with the self-preservation of the republic. As remedies for existing evils he suggests strict personal example, public agitation, stringent laws, and instruction in the public schools on the relations of Sabbath observance to public hygiene.

Aloes.—A high temperature converts some of its active principles into insoluble and inert substances. Especially it decomposes aloin, which forms from fifty to eighty per cent. of aloes. Carbonate of potash assists in the solution of the resin of aloes, and it is well to follow aloetic pills by small doses of liquor potassæ, given in aniseed-water. Some physicians give a dose of potash both before and after the aloes to develop all its powers, which it does without increasing its tendency to gripes. Gum ammoniac with aloes is said to be a better combination than myrrh. In constipation with anæmia and debility there is no better combination than one or two grains of aloes, with an equal quantity of dried sulphate of iron. A favorite prescription with some is: Tinct. aloes socot., U. S. P., ℥ j.; aq. anisi, ℥ iiss.; liquor potassæ, ℥ ij.; ol. anisi, gutt. x. Dose, ℥ j. to iv. Sometimes the excellent and pleasant liquor ammoniæ anisati of the Germans is better.

Dilute Sulphuric Acid.—In some skin diseases, such as lichen, prurigo, chronic nettlerash, few remedies are so successful in relieving the distressing itching, formication, and tingling of the skin. It is applied locally and given internally in ten minim doses. The mouth should be rinsed with a weak alkaline wash after each dose.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 5, 1885.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. ALFRED C. POST, M.D., LL.D., and JOHN T. METCALFE, M.D., were unanimously elected honorary fellows.

DR. FRANCIS V. WHITE made complimentary remarks concerning the candidates for honorary fellowship, who were the only two surviving members of the Faculty of the Medical Department of the University of the City of New York who signed his diploma in 1855.

DR. G. M. SMITH, Chairman of the Committee on Ways and Means, moved that Dr. Willard Parker, Treasurer of that committee, be authorized to pay to the Treasurer of the Board of Trustees of the Academy the sum of three thousand dollars, to be used toward liquidating the mortgage on the property of the Academy.

DR. WILLIAM C. JARVIS then read a paper (see page 284) on

THE ETIOLOGY AND TREATMENT OF NASAL CATARRH, WITH SPECIAL REFERENCE TO THE DEVIATED SEPTUM.

He made the following varieties of deviation of the septum: first, osseous; second, cartilaginous; third, osseo-cartilaginous; fourth, hypertrophic. The cartilaginous occurred the most frequently; the next in frequency was the osseo-cartilaginous.

The special features in etiology to which he directed attention were, first, pressure irritation; second, defective nasal drainage.

Besides the well-recognized causes he spoke especially of heredity, traumatism, and acquired deviation of the septum. He dissented emphatically from the view that diathesis or specific constitutional taint had anything to do with the production of these nasal affections.

Dr. Jarvis then discussed the above questions in their order, after which he directed especial attention to the treatment of the deviated septum, which consisted chiefly in its removal by means of instruments, a large variety of which were exhibited.

DR. F. H. BOSWORTH took issue with the reader of the paper on certain points. He would drop the word nasal catarrh and use the term discharge. He thought the term nasal catarrh covered the entire area of nasal diseases.

With reference to pressure irritation, in the January number of *The American Journal of the Medical Sciences* for the year 1876, Dr. Harrison Allen brought forward this topic in a paper which gave rise to a great deal of comment, the theory being that two mucous surfaces within the nasal cavity lying permanently in contact with each other were likely to be diseased. Dr. Bosworth thought, if that were true, that the result differed from what was seen in any other of the cavities of the body. He had not been satisfied that contact of two mucous surfaces did much harm, and in seeking for the etiology of nasal affections he believed that pressure contact did not enter at all.

He also regarded the mucus from the nasal cavity as harmless as anything could be, and therefore the question of deficient drainage did not become an important etiological factor. Whether the usual nasal discharges were retained or went in one direction or another, he thought, was a matter of secondary importance, as they were essentially harmless.

With regard to the deviated septum, however, he thought that this was the cause, in perhaps nine out of ten cases, of nasal catarrh, but that it was due to pressure contact or deficient drainage he did not believe. He believed that in most cases the deviation was due to disturbance of the normal function of the nose as a breathing cavity, compelling the respired air to pass through a narrowed conduit, giving rise to rarefaction, which led to collapse and dilatation of the venous sinuses.

He did not believe in a diathesis in etiology of nasal catarrh, but thought Dr. Jarvis unfortunately referred to one single condition where struma was pretty well demonstrated as a cause—namely—that carious disease called mollities ossium, in which the palatine arch was changed and gave rise to deviation of the septum.

With regard to the ingenious instruments which Dr. Jarvis had exhibited, the question of instrumental interference resolved itself largely into the tact and skill of the operator. The indications for treatment of the deviated septum were perfectly clear—namely, to remove the obstruction, which was to be accomplished by whatever instrument could be used to the best advantage. He had employed with very satisfactory results a modification of Dr. Lent's subperiosteal saw.

DR. F. A. CASTLE remarked that considerable stress had been laid upon the evil effects of thumb-sucking, by writers on diseases of children, from the fact that this habit was one of the causes of deformity of the arch of the palate, and indeed upper maxilla. It had occurred to him while listening to the paper, that the habit of thumb-sucking might not be so injurious after all; for, if the habit was to result in deformity of the arch of the palate, that give rise to deflection of the nasal septum, then to chronic nasal catarrh, and thereby to the development of the intellect, much of the terror attending the evil habit might be dissipated.

DR. S. O. VANDER POEL, Jr., referred to the treatment of the deviated septum recommended by Dr. John B. Roberts, of Philadelphia—namely—division with the bistoury and the retention of the divided septum in the replaced position by means of a pin introduced through the nostril on the side opposite to the deviation. He had employed this method in five cases with a fair degree of success. The advantages claimed for the method were that it did not leave any large foreign body in the nares, and the patient was not annoyed by the appearance of deformity from wearing any form of retentive apparatus. In the first two cases the results were very satisfactory; in the third and fourth cases the results were also satisfactory; and in all the nostril had been made permanently patent.

DR. D. B. DELAVAN thought it impossible to lay down any fixed rule which was applicable in the treatment of all cases of this character. The plan of treatment, however, which Dr. Jarvis had proposed was one to which he would take exception. He regarded deviation of the septum as due essentially to a distortion of the skeleton of the nose, and while the deflection itself was the factor to which attention was usually directed at first, it would be found that other external changes preceded it, which might become pathological. It was generally believed that the nostril toward the cavity was freer than the other, but while it was probably wider it was not necessarily more patent. He had found, in a large proportion of cases in which there was a deviation of the septum, that there was hypertrophy of the opposite middle turbinated body, and in a close ratio to the amount of the deviation.

Dr. Delavan thought it irrational to remove the mucous membrane and the underlying structures from the convexity of the septum, as it did not relieve the condition of the other nostril, neither did it always give relief, while the condition of the opposite nostril remained unchanged. He had, therefore, suggested that before operating upon the deviated septum it should be determined whether there was an enlarged turbinated body in the wider nostril, and if so, first remove it, and then straighten the septum. Of course, it was impossible to replace the deflected septum with a large turbinated body upon the concave side: for, no sooner was it pressed into place than the enlarged body acted in a way to restore the deformity.

In cases of deflected septum, the difficulty was far

more extensive than was usually supposed. The deformity was so extensive that no ordinary operation would relieve the patient, and it required marked diagnostic skill, in many cases, to determine whether or not the remedy which would remove the difficulty could be applied easily.

Dr. A. C. Post suggested that, in cases of stenosis of the nasal passage from deviation of the septum, where it became necessary to remove a portion, the operation could be facilitated by a transverse division of the columnæ, which could afterward be replaced with sutures, and not add to either the difficulty or the gravity of the operation.

Dr. Jarvis, in closing the discussion, said that he employed the term, "nasal catarrh," because it was well known and more familiar than other terms which had been used. As to pressure irritation, he believed there was no doubt that such a condition existed. He had made his experiments independently, with a study of the normal physiological action of the turbinated tissue, the size of which was constantly changing.

With regard to the nasal mucus, he distinctly stated that mucus of the normal specific gravity did no harm, but when it became thickened and changed in character, it fell into the larynx, where it became equivalent to a foreign body, and produced, as was well known, not only congestion, but marked pathological changes.

With reference to the malformation of which Dr. Delavan had spoken, he believed that it could exist, although he had seen but two cases which he would term turbinated shell associated with deviation of the septum. If an osseous formation existed, it was proper to remove it, and treat the deflected septum afterward.

Concerning Dr. Roberts' method, spoken of by Dr. Vander Poel, he had not succeeded in getting his patients to submit to it as readily as to the operation which he usually performed.

Dr. George G. Hopkins, of Brooklyn, then gave the history, and exhibited microscopic specimens, of

A RECURRENT FIBROMA OF THE BREAST,

removed from a girl seven and eleven years of age, respectively, at the time the operations were performed. The tumors were removed under antiseptic precautions. The chief interest in the case was the early age at which the disease had manifested itself.

The Academy then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 11, 1885.

John A. Wyeth, M.D., President, in the Chair.

(Continued from page 276.)

DIPHTHERITIC CROUP—TRACHEOTOMY—RECOVERY.

Dr. Ripley presented a cast of the trachea and upper part of one of the bronchial tubes removed from a child who was taken with diphtheritic croup early in February, and on the second day Dr. Charles Milne was called, when he found considerable dyspnœa, which increased, and on February 3d, Dr. Ripley was called and performed tracheotomy. Although the disease had been exceedingly rapid, the trachea was filled with muco-pus and membrane. The child breathed perfectly easily after the operation and did well through the next day. Early in the morning of the second day after the operation dyspnœa was again very urgent; the child was suffering so severely at four o'clock in the morning that he was called, and with Dr. Milne they removed both tubes, and succeeded in removing a cast of the trachea having attached to it a cast of one of the limbs of the bronchial bifurcation. Several other large pieces of membrane were also removed, the tubes were replaced, and the child breathed easily. From that time the case progressed favorably, the tubes had been removed, the wound was granulating, and there was fair promise of complete recovery.

Dr. Gerster asked if, when the trachea was first opened, before the canula was introduced, any membrane was noticed.

Dr. Ripley replied that the operation was performed with a good light and great deliberation, and the trachea was thoroughly examined, and no membrane was detected.

TUBERCULOSIS OF LUNG—TUBERCULAR ULCERATION OF LARYNX AND PHARYNX—MEASLES—CATARRHAL PNEUMONIA.

Dr. Van Santvoord presented specimens with the following history: The patient, M. C——, a foundling, had been an inmate of the Randall's Island Infant Asylum for several months. During that time it had been cachectic and had suffered from cough. During the summer of 1884 it had an attack of impetigo contagiosa, it being one of a number of cases. The cachectic state of the child and the fact that the eruption was hemorrhagic and more pustular than in the other children, gave rise to the suspicion that the cutaneous disease was a pustular syphilide. The fact that its attendant had two or three of the characteristic vesicles on her arm, that the disease followed the same course as in the unquestionable cases of impetigo contagiosa, causing no deep ulceration, and that no history pointing to syphilis in the infant could be obtained, rendered specific disease improbable. The swelling of the third phalange of the index-finger of the left, and the middle metacarpal bone of the right hand existed on admission. Ulceration of the metatarsal bone existed for some weeks, of the phalange only a few days before death. The child suffered from dysphagia for some time before her death, which resulted from measles, complicated by extensive catarrhal pneumonia, at the age of thirty-one and one-half months.

Post-mortem, three days after death.—Child small for her age, emaciated, integument yellowish. Numerous thin masses of desquamating epithelium, about one-eighth of an inch in diameter, on a slightly hemorrhagic base were observed, chiefly on the arms. The third phalange of the left index-finger was about one-half larger in diameter than its fellow, and fusiform in shape. A round opening, with smooth red edges, about one-twelfth of an inch in diameter, on the ulnar side of the finger lead down into the interior of the bone. Its bottom was a yellow slough. On section the bone was found to be shorter than its fellow. The section was biconvex in outline. The medullary tissue about the cavity was yellow and soft. Toward the epiphyses it was redder and softer than normal. The middle metacarpal bone of the right hand had a large ulcer, similar to the above, about one-eighth of an inch long by one-fourth of an inch broad, leading into the interior of its shaft at its middle from the back of the hand. At the bottom of this ulcer was a loose, carious piece of spongy bone, equal to about one-fourth of the shaft. A narrow strip of apparently new bone was seen, on section, connecting the epiphyses. As the strip approached either extremity it was broadened into a wedge-shape, by what appeared to be residual portions of the cancellous tissue. The bone, as a whole, was curved forward. Brain: normal. Larynx and pharynx: Three or four small deep ulcers, size of a large pin-head, were seen on the posterior pharyngeal wall. Ulcers penetrating the mucous membrane were observed on the tip of the epiglottis, both the aryteno-epiglottidean folds, the posterior wall of the larynx, and on the upper and posterior surface of both vocal cords. The non-ulcerated portions of the cord were red and thickened.

Lungs: Trachea and bronchi much injected. Both lungs adherent throughout by old adhesions. The left upper lobe was honeycombed, with cavities containing pus, small cavities with considerable old fibrous thickenings existed in the right upper lobe. Extensive consolidation by recent broncho-pneumonia existed in the non-tubercular parts of these lobes. In the lower lobes a few small cavities and considerable foci of recent lobular

pneumonia existed. Heart: Normal. Liver: Pale, with isolated patches of yellow parenchyma on cut surface. One small grayish nodule on surface. Kidneys: Pale. Spleen: Normal. Intestines: Slight enlargement of solitary follicles. Mesentic glands not enlarged.

Dr. Van Santvoord regarded the case as unique on account of the age of the patient. In looking up the subject of tubercular laryngitis in young children he had found in Dr. Smith's work the statement made that he had not seen a case in a child of this age. Rilliet and Barthez had also said that in three hundred autopsies it had not been found in children under three years of age. In the specimen there was an ulcer at the tip of the epiglottis, and he thought that form of ulceration was rare in syphilis.

Dr. Ripley thought that Dr. Van Santvoord was mistaken on that point.

The specimen was referred to the Committee on Microscopy.

Dr. S. J. McNutt presented specimens accompanied by the following history:

COMPLETE DESTRUCTION OF ONE LUNG IN THE COURSE OF PULMONARY PHTHISIS IN A CHILD.

I have here the thoracic and the abdominal viscera from a child of four and one-half years whose autopsy I made at the Morgue and whose history I do not know, not having been able to obtain even the death certificate of the case.

The body was extremely emaciated, and upon opening the chest both lungs were found to be adherent through their entire extent. Over the right lung the adhesions could be readily broken. The middle two-thirds of the anterior surface of the left lung also was only slightly adherent. Upon breaking these adhesions the left lung presented the appearance of a single distended sac occupying both lobes, and covered by a smooth, opaque, bluish-white membrane dotted with irregular yellowish-white patches. At the apex of the left lung the pleura was greatly thickened, so as to form a kind of hood. The adhesions here could not be broken down but had to be cut away from the periosteum of the ribs and the intercostal tissues. Posteriorly and at the side the adhesions could be torn, but only with considerable effort, and at the base, where the lung came in contact with the diaphragm and the pericardium, separation could not be effected, and these parts were cut away with the lung.

There was no appearance of external perforation or cicatrix on either lung. There was in neither pleural cavity air, gas, blood, or pus.

When the lungs were removed from the cavity there was a quivering sensation conveyed upon grasping the left lung, and when the larynx was cut from its attachments a considerable amount of a dirty grayish fluid escaped, with a sensible diminution in the size of the left lung and a partial collapse of its walls.

Continuing the examination of the left lung, every part of the pleural surface which was not covered by a thick fibrinous deposit presented fine semi-transparent nodules, pin-point in size, embedded, and yet so near to the surface as to be distinctly seen. They were the most abundant over the lower anterior tongue and on the surface toward the diaphragm. Surface of the right lung also was studded with these shining masses through its whole extent, but most abundantly between the lobes. The pleura covering the diaphragm was similarly studded. Upon the costal pleura, where it had not been stripped off, these masses were found, but of much larger size.

Upon opening into what represented the left lung there was found a sac, which was partially filled with a dirty, greenish-yellow, thin, purulent fluid mixed with cheesy masses and shreds of tissue. The cavity was irregular in shape and involved the entire lung. A partial septum separated what had been the upper and the lower lobe, also a partial thin septum divided what had been the lower lobe into an anterior and a posterior portion, and in this septum was the bronchus to that part of the lung. It opened into the cavity. Near it were what appeared to be the remains of pulmonary vessels. The walls of the sac were ragged, but there were no traces of vesicular tissue nor any crepitation in any part. There were in them areas of thickened tissue, with cheesy nodules, a few isolated trabeculæ, and hanging necrotic shreds. All of the bronchi opened into the sac, their free extremities presenting irregular ulcerations of the mucous membrane. There were also small superficial ulcerations prolonged into the main bronchus up to the lower part of the trachea. In the larynx there were also small points of ulceration, the greatest aggregation being just below the vocal chords.

In the right lung the only portion which crepitated under the finger was the lower anterior half of the middle lobe. Here also there was marked interstitial emphysema, and in the remainder of the lung there were spots of atelectasis, with many cheesy masses, varying from the size of a pigeon's egg to that of a small pea, surrounded by more or less inflammatory tissue. On section a large number of these nodules showed cavities filled with pus. There was considerable œdema posteriorly in the lower lobe.

There was more or less hyperplasia in all of the bronchial glands, which varied in size from that of a filbert to that of a small pea. A number on section showed cheesy degeneration, while others had cavities which were filled with pus.

There was the normal amount of fluid in the pericardium. The heart was square in shape, of a pale color, and a yellow tinge. The wall of the right ventricle measured one-twelfth of an inch in thickness, its cavity being much larger than that of the left. The wall of the right auricle was extremely thin, presenting the appearance of a delicate membrane. Its cavity was twice as large as that of the left side.

The spleen was hard and heavy. Its edges were rounded and its cut surface gave a smooth, dark, transparent appearance.

The liver was very much enlarged, particularly in its antero-posterior diameter. It was firm to pressure, its edges were rounded, and upon section it had a transparent waxy appearance with a yellow tinge.

The kidneys were small, pale, and of a yellowish color, similar to that of the liver. The liver, spleen, and kidneys all showed markedly the iodine reaction indicative of an amyloid change.

There was marked ulceration throughout the intestinal tract, particularly in the lower part of the small intestine and in the colon. These ulcers were rounded and irregular in shape, with elevated edges, and inclined to extend laterally, in some parts of the colon almost encircling the gut.

The brain was very anæmic, but there were no tuberculous masses to be seen by the naked eye in any part. Throughout the body, however, in the trabeculæ of the lungs, in the liver, in the spleen, in the kidneys, and throughout the mucous and the serous layers of the intestine, a very low magnifying power brings into view myriads of little shining transparent granular bodies.

A particular point of interest in this specimen is the total destruction of one lung, and especially its coexistence with infiltration and degeneration through the greater part of the lung of the opposite side. In this case the function of one lung was entirely abolished, the only portion of the opposite lung which could be utilized for respiratory purposes being the lower one-half of the middle lobe, anteriorly, and even in this part there was marked interstitial emphysema.

We know of no case upon record in which life has been prolonged until there had occurred so great a destruction of aërating tissue as is present in this specimen. Two cases have been recorded which in the amount of

the destruction resemble this, but in which the pathological process was different. A case is reported by Dr. W. H. Porter, in the "Transactions" of this Society, 1881, in which the left lung was compressed into a small mass, not larger than a man's fist, in a state of complete carnification, the result of a pleurisy with effusion and empyema, and in which the right lung was a group of small cavities surrounded by zones of cheesy masses. An unabsorbed pleuritic effusion had been the primary trouble in this case. Beverley Robinson also, in 1881, presented to you atrophy of one lung found in a man, aged thirty-five. Both lungs were firmly adherent to the chest-walls, the right was markedly emphysematous. It had fibrous phthisis in the upper half, while the upper part of the middle lobe was tubercular. The whole lung was enlarged so that it extended into the left side of the chest, while the left lung was contracted to the size of the closed fist; it was cheesy and had an entire obliteration of air-cells. Dr. Robinson says that the atrophy of the left lung was probably due to the contraction of an hypertrophied pleural membrane. The President, Dr. Satterthwaite, remarked of this case, that in only one previous case had he seen so complete an absence of the aërating structure as was manifested in the specimen presented. In this mention Dr. Satterthwaite referred to a case reported by Dr. Alonzo Clark (MEDICAL RECORD, January 2, 1875). This case was designated as a case of destruction of the lung by inflammatory phthisis. The patient was a male, twenty-three years of age, with a history of pulmonary hemorrhage, followed by a pneumonia involving the whole of the left lung, and which did not resolve. Nine months later a cavity was discovered in the left lung. At the end of two years and ten months after the time attacked he died of hemorrhage. In commenting on this case Dr. Clark says that it is common enough for people to say of themselves, or of others, that one lung was, or is, all gone, but examination has so frequently contradicted the statement that he, for one, had about persuaded himself that death must occur before so much devastation could be accomplished; but here was a case, really a case of phthisical inflammatory destruction of one lung.

It is an interesting point to notice how small an amount of lung-tissue can support life. Dr. Clark's patient is said to have attended to his business a greater part of the time, and his non-professional friends thought him almost completely restored.

The marked amyloid degeneration found in our case will probably account for the marked dilatation of the right heart instead of hypertrophy, from the fact that the blood was so deteriorated that the compensatory growth of muscular tissue could hardly occur, at least not sufficiently to overcome the great interference in the pulmonary circulation. From this obstruction also would happen the setting back of the current of venous blood, with the consequent congestion and enlargement of the kidneys, liver, and spleen.

A second interesting point is the question of priority between the generalized tuberculosis and the abscess in the lungs. Did we have here first a pneumonia with infection and breaking down and the scattering of its product, and the establishment of these scattered foci as a secondary result?

A third interesting point is the fact that of the cases here collected in our own only did this great destruction of lung-tissue occur in a child.

DR. W. M. CARPENTER referred to two specimens which he had seen recently, one exhibited by Dr. M. N. Miller, Curator to Charity Hospital, and the other by Dr. H. P. Loomis, Assistant Curator to Bellevue Hospital. In the first all that was left of one lung were the root of the organ with stumps of blood-vessels, some bronchi, and shreds of fibrous tissue. The opposite lung was emphysematous, and the seat of an acute process which terminated life. In the second specimen essentially the same condition of things existed, with the addition of advanced phthisical process with cavities in the opposite lung.

Both specimens were from the bodies of adults. Dr. McNutt's specimen was interesting because of its occurrence in so young a subject.

DR. RIPLEY thought that the ability to tolerate any disease depended upon the rapidity of its invasion. The more slowly the lung was invaded the more the patient was enabled to tolerate the disease.

DR. FERGUSON presented a specimen in behalf of a candidate, and the PRESIDENT presented specimens of the comma bacillus obtained from Dr. Billings, of Boston, who had received them directly from Dr. Koch, of Berlin.

The Society then went into executive session.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 6, 1885.

A. BRAYTON BALL, M.D., PRESIDENT, IN THE CHAIR.

A DISCUSSION was opened upon the subject of

PRACTICAL CONSIDERATIONS REGARDING THE ACUTE INFECTIOUS FEVERS,

especially scarlet fever.

The first question raised was

WHETHER SCARLET FEVER IS CONTAGIOUS DURING THE STAGE OF INCUBATION,

before the period of invasion, and, if so, to what extent.

DR. BEVERLEY ROBINSON said that his impression was that he had seen cases in which the contagion had evidently been carried during the incubative period. He thought such cases very difficult to prove and very exceptional.

DR. CLEMENT CLEVELAND had no experience to warrant him in believing that scarlet fever was contagious in the period of incubation, but he had the impression that it was contagious during that time.

DR. KINNICUTT had met with two cases in the past several years, which might be of interest as showing the slight power of the contagion during this stage. At a children's party, numbering thirty or thirty-five, one child was present who, not more than three hours afterward vomited and showed other signs by which scarlet fever was diagnosticated. Of the other children at the party, a large proportion had never had scarlet fever, and none of them took the disease.

In the second instance, one child sat for nearly the whole afternoon with his arm about another who was complaining of not feeling well. Six hours later, Dr. Kinnicutt saw the sick child and diagnosticated scarlet fever. The other child did not take the disease, though he had never had it.

These cases, the speaker admitted, furnished only negative evidence.

DR. JAMES B. HUNTER related the history of a case furnishing similar negative evidence.

THE PRESIDENT thought such negative evidence not very valuable, because it is well known that scarlet fever is not communicated with the same ease as small-pox or measles. He remembered an instance, years ago, where two children passed the night together. One of them broke out with scarlet fever two days afterward, and the second four or five days later. It is to be remembered, however, that the contagium of scarlet fever has a remarkable tenacity for articles of clothing. There was no doubt that the disease is much more contagious in later stages.

DR. E. G. JANEWAY had never met a case illustrating the contagiousness of the incubative stage.

DR. S. BARUCH had met with a case similar to those of Dr. Kinnicutt. Three children slept one night in the same room. A short time after two of the children de-

veloped scarlatina; the third did not, until five weeks later, when the first were convalescent.

The second question presented was:

WHAT MEASURES ARE DEEMED NECESSARY DURING THE SICKNESS OF THE SCARLET FEVER PATIENT TO PREVENT THE SPREAD OF THE DISEASE?

Dr. Beverley Robinson said that he adopted the usual means of isolation. He had the meals and medicines served by one person who would not come in direct contact with other members of the household.

He used disinfectants, usually the chlorides, but in rather a perfunctory and routine way, and he did not feel now that they did much good. The main thing was to secure good ventilation, which is the best disinfectant. He put the disinfectant over the bed-clothes, in the fecal and other discharges, and placed it about the room.

Dr. Clement Cleveland tried to make isolation as complete as possible. He believed in the great importance of ventilation. He usually had a spray of carbolic acid ʒ j. to Oj., or of a bichloride solution frequently used in the room. All the clothing taken from the patient was disinfected at once. As soon as the eruption was out he had the skin anointed with carbolized vaseline, gr. v. to ʒ ij. The skin was bathed every day, and after this reanointed.

Dr. S. Baruch said that his practice was isolation and plenty of air. He had

GIVEN UP DISINFECTANTS

in the room entirely. He believed that they did no good, and did harm by encouraging a false sense of security, to the exclusion of ventilation, etc. He had all the clothing after use soaked in a chloride of zinc solution, until it was ready to be washed separately.

Dr. George L. Peabody followed very much the same practice as Dr. Baruch. When so requested, he sometimes suspended sheets in the room wet with a disinfectant solution. In one recent case he had had the stools disinfected, although he was not clearly of the opinion that the contagion was carried in them.

Dr. E. J. G. Janeway advised disinfecting the excreta, because infectious material from the skin and elsewhere was apt to get mixed with them.

Another point was, if possible, not to have the clothing taken through the house. He had them thrown out of the window into the yard below, after having them thoroughly boiled or soaked in a disinfectant solution, *e.g.*, chloride of zinc made up by the Board of Health rules. Beyond this, he went no further in the use of disinfectants, except that he took great care about the patient, that all articles which had come in contact with the skin or had been used by the patient be burned up or disinfected; trusting also to thorough disinfection after the patient got well. He did not know that the carbolic acid did much good, but vaseline is useful if rubbed into the skin. He thought it a good plan, when there were other families on the same floor, to hang a sheet dampened with a disinfectant over the door. He preferred burning the rags, and as far as possible the clothing used about the patient, to taking the risk of inefficient disinfection.

Dr. Kinnicutt believed in isolation, ventilation, and thorough disinfection. He recommended that the clothes, unless thoroughly disinfected, be thrown out of the window instead of carried through the house.

Dr. James B. Hunter attached much importance to

SANITARY PORTIÈRES,

or sheets hung over the door and kept wet with carbolic acid solutions. He had the clothing disinfected and put in a separate wash.

The President thought that there was good reason for believing that the infectious poison was a blood poison, and that it passed off in all the excreta. Therefore their disinfection was a rational one.

Dr. Baruch asked if any gentleman had had any experience with instances of

CARBOLIC ACID POISONING

as the result of too vigorous disinfection. In a case of his own the mother was very anxious, and sprinkled carbolized water over the floor and upon wet sheets so liberally that the patient had black urine for two days. There was no albumen, and there were no bad symptoms.

Dr. Cleveland asked the opinion of the members as to the value of

ANOINTING THE BODY.

He thought it very important.

The President believed it to be a very prevalent practice.

Dr. Kinnicutt thought that it relieved very greatly the irritation.

The third question proposed was:

HOW LONG THE SCARLET FEVER PATIENT SHOULD BE ISOLATED.

Dr. Robinson said that his rule had been the usual one of isolating for six weeks. This furnished a good working basis. He had known of cases which had been isolated for a longer time and yet had carried the disease. He felt, therefore, that there was no definite period which could be absolutely fixed as safe.

Dr. Cleveland never felt willing to take the responsibility of removing the isolation and giving a positive assurance that there was no further danger.

He followed about the same practice as Dr. Robinson as to limit of time.

Dr. Baruch said that the principal trouble was in preventing the too early use of the infected room.

THE ROOM,

not the child, was the source of danger.

Dr. Janeway doubted if the whole of the desquamative period was contagious. Carpenter claims that scarlatina is not contagious after the tenth day. Some years ago he had a case which made him take a different view to that which he had held formerly. A woman living in a tenement-house was taken with scarlet fever. The rest of the family, including children, were sent away for three weeks. While the woman was still desquamating freely the family insisted on returning. The rooms were thoroughly disinfected, and the woman given two baths. The family then returned and none caught the fever.

Dr. Janeway thought that the danger in the desquamating stage was more about the room or clothes which had not been thoroughly disinfected.

He waited until desquamation was complete, and then had the head shampooed twice.

Dr. Kinnicutt said that careful thermometric observations showed that a slight elevation of temperature persisted into the third and fourth weeks in a large number of uncomplicated cases. This would seem to indicate that the morbific action was not exhausted, although the more palpable symptoms of the disease had disappeared. Certainly as long as this elevation of temperature exists, we must expect that there is danger of contagion from the person.

Referring to the opinion that intercourse should not be permitted until a week after desquamation had ceased, the speaker said that cases had been reported, in which desquamation had lasted until the seventy-seventh day. In such cases, Dr. A. Jacobi had expressed the opinion that the *prolonged* desquamation was free from danger, as it might be regarded as a simple dermatitis. Dr. Carrol, of the State Board of Health, had recently expressed a similar view in an interesting paper, a view in which the speaker fully concurred. Dr. Kinnicutt regarded forty days as the full limit of time in which *contagion from the person* was probable.

Dr. Hunter reported a case where scarlet fever had been conveyed by a box of toys, sent down to Long Branch, from a sick patient in New York. His rule as to duration of quarantine was six weeks.

The President said that this period had recently been adopted in England by a convention assembled for the purpose of discussing these questions.

Dr. Janeway said that he did not feel afraid of contagion from the person after the first month. In practice, however, he would probably advise a longer quarantine.

The fourth question was

WHETHER THE PHYSICIAN WHO IS ATTENDING A CASE OF SCARLET FEVER OUGHT TO TAKE MIDWIFERY CASES.

Dr. Robinson thought that, as a matter of prudence, the physician ought not to attend midwifery cases and scarlet fever at the same time. Still, he did not think that there was a great deal of danger of either the mother or child taking the fever.

Dr. Cleveland said it was his rule not to attend scarlatina and obstetrical cases at the same time.

Dr. Baruch did not believe that the scarlet fever poison could cause puerperal fever, and did not think that physicians could convey puerperal fever from scarlet fever cases. He thought that, practically, it would very much limit the work of the general physician, if he had to give up obstetrical cases whenever he had a case of scarlet fever. He did not think that scarlet fever could be conveyed by a third healthy person, and quoted Henoch's statement in support of such a view.

Dr. Janeway spoke of the

ADIRONDACK REGION

as the best place to study the spread of the infectious fevers. People lived widely separated, and yet were in constant inter-communication. Scarlet fever and diphtheria had travelled through that region.

Dr. Hunter thought it not advisable to attend scarlet fever and obstetrical cases at the same time. He would not perform a serious surgical operation, such as ovariotomy, while attending a scarlet fever patient. He looked upon a puerperal woman as very much in the same state as a person upon whom a surgical operation had been performed.

Dr. C. L. Dana related an instance in which a physician had brought the scarlet fever into his own household, as illustrating the positive fact that physicians may be carriers of the infection. He thought it important to know to what extent they could carry the poison, and what practical means might be adopted to lessen the danger.

Dr. Cleveland said it was his practice always to make calls on such patients last, and then to change his clothes.

The President had never seen any bad results from physicians taking confinement cases while attending scarlet fever, and he thought the danger

GROSSLY EXAGGERATED.

A great deal of what is called scarlet fever in puerperal women he believed was not scarlet fever at all.

The fifth question was

AS TO WHETHER DEFECTIVE SEWERAGE HAS ANYTHING TO DO WITH SCARLET FEVER.

Dr. Janeway did not believe that there was any proof at all that defective sewerage has anything to do with scarlet fever. One sees the most defective sewerage arrangements and no scarlet fever, while on the other hand one finds scarlet fever where the sewerage is perfect. The same was true with regard to slaughter-houses. Philadelphia and Boston had their slaughter-houses moved away, but without affecting the amount of scarlet fever.

OUR LONDON LETTER.

(From our Special Correspondent.)

COMPARATIVE PATHOLOGY—LUNG DISEASES IN CAPTIVE WILD ANIMALS—THE HUNTERIAN ORATION.

London, February 21, 1885.

At the last meeting of the Pathological Society the event of the evening was the reading of a paper by Mr. Bland Sutton on the subject of "Lung Diseases in Wild Animals." Although quite a young man, Mr. Sutton has already acquired no inconsiderable repute as a comparative pathologist. To some of his researches I have previously alluded. His present paper attracted an unusual amount of interest.

Mr. Sutton's investigations have shown him that the popular opinion that captive wild animals die from tuberculosis is erroneous. He found, though, that a considerable number suffered from pulmonary affections. In the Zoölogical Gardens, from October, 1881, to December 31, 1884, the total number of deaths was 2,779, of which number 583 were mammals. Of the mammals 303 were quadrumana, including 7 anthropomorphous apes. Of these mammals only 5 died from pulmonary tuberculosis and only 1 case of general tuberculosis occurred. All these tuberculous animals came from the tropics. In several of them the lungs had been examined for bacilli and they had been found to be present literally in millions. Twelve cases of pneumonic phthisis had been seen, and more bacilli had been found in them than in cases of tuberculosis, but even if we included these cases under tuberculosis, which Mr. Sutton seemed disinclined to do, that disease was far from being a frequent cause of death in wild animals kept in captivity.

Mr. Sutton then proceeded to discuss the fatal diseases of animals in confinement. He remarked that each group of animals had certain forms of chest affections common to it. Primates, excluding man, suffered from bronchitis, atelectasis, and lobular pneumonia. Carnivora were very liable to double pleurisies, lobar pneumonia, and bronchitis. Ruminantia suffered from bovine tuberculosis (Perlsucht), bronchitis, and "worm" bronchitis. In reply to a question, Mr. Sutton said that about thirty per cent. of the quadrumana he had seen suffered from lung disease. He observed that, zoölogically speaking, bronchitis was widely diffused. This was accounted for by the vicissitudes of the English, as compared with the tropical, climate from which many of the animals had been brought.

Mr. Sutton said that, so far as tuberculosis had been concerned, birds had been excluded from this report, yet there was one diseased condition peculiar to them which was of great interest, and the exact nature of which had not previously been noted by any previous observer. The bronchia of birds communicate with a series of membranous air-sacs. He had found that the lining membrane of the sacs was, especially in water-fowl, liable to undergo inflammation giving rise to exudation. This coagulated and often formed a layer half an inch thick, providing an excellent nidus, in which the mould penicilium could flourish and form a thin layer extending through the whole series of air-chambers. The presence of the mould had been observed by Hunter, Owen, Robin, and others, but the exudation had been overlooked. This condition was exceedingly interesting, because the penicilium did not confine itself to the air-sacs, but even permeated the intercapillary air-spaces of the bird's lung, which corresponded to the alveoli of the mammalian lung. Mr. Sutton asked whether, in view of these facts, it was a matter for wonder that in the human lung, vegetable organisms (bacilli), a fraction of the size of the spores of penicilium, but requiring similar conditions for existence, should occur?

The Hunterian Oration at the College of Surgeons was

delivered on Saturday last by Mr. Marshall, F.R.S., Past President of the college. According to custom, the first part of the address was devoted to making some reference to distinguished members and Fellows who had died during the preceding year. Mr. Marshall referred to Robert Druitt, Allen Thomson, Cæsar Hawkins, and Erasmus Wilson. He then took up his subject proper, viz., Hunter, his life and works. There were, he remarked, two methods of constructing biography, viz., one to pursue the well-trodden path of sketching a career from the cradle to the grave, the other to reverse the order, follow an upward course, and thus pass from the later and better-known periods to the earlier and less known—or even unknown—moments of any individual existence. As in the case of a river, in the upward struggle against the stream, with its halts and delays, we had larger opportunities of becoming familiar with its opportunities, its shoals and rocks, its rapids and cataracts, and so on.

Mr. Marshall said he preferred, if it were not too presumptuous, to adopt another method, and imagine Hunter now with us, and try and point out the attitude he would assume in regard to the active work and salient opinions of our own times. He did not doubt that Hunter would first wend his way to the museum and feel gratified at its great extension and present condition. As to the college library, he suggested that as Hunter said, "I do not read many books," he might be comparatively apathetic to its extension. The advances made in comparative anatomy would be welcome to him. The revelations of microscopical research would fill his mind with amazement and delight, and he would be struck with admiration at the appliances available in modern physiological laboratories. Hunter was a great vivisector, and anæsthetics were then unknown, but he would be sure to approve their use now. Hunter would doubtless appreciate the modifications of the Cuvierian classification found necessary by succeeding zoölogists. He would probably give in his adhesion to Darwin.

The advances made in scientific and practical surgery would receive his eager acceptance, for although he looked upon operations as a tacit admission of inability to cure, and said they should be approached with a sacred dread and reluctance, we might be sure that the new and bold procedures which have been crowned with success with the aid of anæsthetics would be approved and adopted by him.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 1, 1885, to March 7, 1885.

Byrne, Charles C., Major and Surgeon. Ordered to Department of the East on expiration of his present leave of absence. S. O. 50, A. G. O., March 3, 1885.

Woodruff, Ezra, Captain and Assistant Surgeon. Ordered for duty at Fort Maginnis, Montana Territory. S. O. 23, Department of Dakota, February 25, 1885.

Porter, J. Y., Captain and Assistant Surgeon. Leave of absence further extended fourteen days on account of sickness. S. O. 51, A. G. O., March 5, 1885.

Ewing, C. B., First Lieutenant and Assistant Surgeon. Having relinquished unexpired portion of leave of absence, ordered for temporary duty in the field. S. O. 23, Department of the Missouri, March 2, 1885.

Raymond, Henry I., First Lieutenant and Assistant Surgeon (recently appointed). Ordered for duty in Department of California. S. O. 50, A. G. O., March 3, 1885.

Carbonate of Ammonia has gained much credit in the gastric disturbance which follows a drinking bout or debauch. The aromatic spirits of ammonia, curiously called sal volatile by the English, is much used in chronic bronchitis.

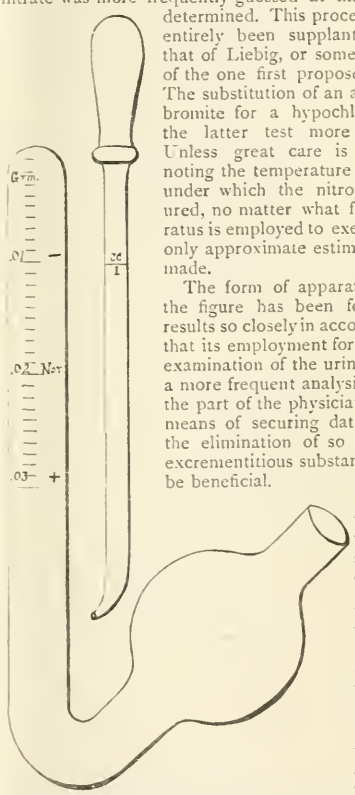
New Instruments.

APPROXIMATE QUANTITATIVE ESTIMATION OF UREA.

By CHARLES A. DOREMUS, M.D., Ph.D.,

PROFESSOR ADJUNCT TO THE CHAIR OF CHEMISTRY AND TOXICOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

The old method of adding nitric acid to urine in order to estimate the quantity of urea, a method which commended itself to the medical profession through its apparent simplicity, was at best only approximate. It involved frequently the evaporation of the urine, a tedious process, and the degree of concentration necessary to bring about the formation of the crystals of urea nitrate was more frequently guessed at than accurately determined. This process has almost entirely been supplanted by either that of Liebig, or some modification of the one first proposed by Davey. The substitution of an alkaline hypobromite for a hypochlorite renders the latter test more satisfactory. Unless great care is exercised in noting the temperature and pressure under which the nitrogen is measured, no matter what form of apparatus is employed to execute the test, only approximate estimations can be made.



The form of apparatus shown in the figure has been found to yield results so closely in accord with theory that its employment for rapid clinical examination of the urine may lead to a more frequent analysis for urea on the part of the physician, and be the means of securing data concerning the elimination of so important an excrementitious substance which will be beneficial.

The manipulation of the ureometer is simple in the extreme. By inclining it the long arm may be filled with the hypobromite to the bend at the bulb. By means of the nipple pipette a measured volume of the urine (1 c.c.) is injected slowly up the long arm by compressing the nipple. A rapid decomposition of the urea takes place, the bubbles of nitrogen rising in the long arm, while the displaced liquid flows into the bulb, which serves as a reservoir. With a little care the urine may be delivered at a rate that permits the decomposition to take place without loss of gas. The graduation on the glass indicates the weight of urea in the urine used. Two forms of the apparatus are made, one graduated to read fractions of a gramme (0.00 to 0.03 per 1 c.c. of urine), the other to show grains of urea in the fluid ounce of urine. When the volume of urine passed in twenty-four hours is known the calculation of the analysis is very easy. Total quantity of urine voided, 1,600 c.c.; urea in 1 c.c. of urine (result of analysis), 0.024 grammes; urea in 1,600 c.c. = 0.024 × 1,600 = 38.4 grammes. When the centesimal graduation is used the weight of urea in 100 volumes of urine is ascertained by multiply-

ing the result of the test by 100. This gives what is commonly termed the percentage of urea. This is not strictly correct, but the true percentage can be calculated when the specific gravity of the urine is taken thus: Specific gravity of urine, 1.020; urea in 1 c.c. of urine, 0.02 grammes; 100 c.c. of urine would contain 2 grammes of urea; 100 c.c. of urine would weigh 102 grammes if the specific gravity was 1.020, therefore,

102 : 100 :: 2 : x = 1.96, the true percentage.

When the tube graduated in grains is used the calculation of the percentage is a more complicated arithmetical problem. The ounce contains 455.7 grains. From this, the specific gravity, and the result of the analysis, the computation can be made.

The hypobromite solution is prepared according to the formula of Knop, by dissolving 100 grammes of sodium hydrate in 250 c.c. of water. This solution may be kept in a bottle with a paraffined stopper. Bromine is mixed with this in the proportion of one volume to ten; 2 c.c. of bromine with 20 of the sodium hydrate will suffice for two tests. After the bromine has united with the alkali the liquor is diluted with its own volume of water.

When using English weight six ounces of sodium hydrate are dissolved in a pint of water to make the alkali. The bromine should be added to this in the proportion of one to ten, and the liquid diluted with its own volume of water. A fresh, good, hypochlorite will serve for the hypobromite when the latter cannot be obtained.

The normal quantity of urea voided is two per cent. or .02 grammes per c.c. or 10 grains per ounce. The elimination of a diminished or increased quantity of urea is speedily determined by the use of the apparatus.

Messrs. Eimer & Amend supply either form at a very moderate price.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 7, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

March 7, 1885.....	0	2	12	0	25	23	0	0

Climatic Health Resorts.—Accurate, full, and unprejudiced information respecting health resorts being at present very difficult to obtain, the contributor of the articles on *Climate* and on *Health Resorts* for "A Reference Handbook of the Medical Sciences" will be glad to receive, from those competent to furnish them, any facts or data bearing upon these subjects which they may be disposed to communicate. Address (at earliest convenience), "Climatology," Care of Messrs. Wm. Wood & Co., 56 Lafayette Place, New York City.

Intestinal Strangulation—Symptoms Masked—Curious Fatty Deposit in Peritoneum.—Dr. C. M. Fenn, of San Diego, Cal., was called to see a butcher, thirty-five years of age, of intemperate habits, and corpulent in body, who, while driving along the street, was suddenly seized with severe pain in the abdomen. He went home to bed and was treated with morphine injections, repeated for thirty-six hours, without relief. Dr. Fenn was then called in. He found the patient suffering great pain, especially in the left hypochondriac region. He had vomited two or three times, but not stercoraceous matter. His abdomen was not tympanitic nor markedly tender. The bowels had moved twice. Believing the spleen to be at fault, Dr. Fenn ordered laudanum fomentations over it, followed by a blister and morphine. The pain gradually yielded, and the patient improved very much. A few hours later, however, he rapidly sank and died. Post-mortem showed the thoracic organs normal; the spleen was three times its normal size, adherent to the abdominal wall, "and showed other signs of acute parenchymatous inflammation."(?) "Traces of peritonitis also, chiefly confined to the left hypochondriac region, were visible. In the upper and posterior portion of the umbilical region there was discovered a mass of sphacelated intestine, the relations of which could not be determined after the rude displacement of the adjacent viscera. My impression at the time was that it included a portion of the splenic flexure of the colon. The liver was typically cirrhotic, or a gin-drinker's. The abdominal cavity, from the diaphragm to the floor of the pelvis, was lined, or inlaid, with a substance resembling solidified tallow, more than an inch thick. It presented the glistening, yellow appearance characteristic of the fat of slowly fattened animals. A more complete cast of the cavity or cavities could not have been made with gypsum. The kidneys and other viscera were enveloped in masses of the same, from which it became necessary to "shell them out," before they could be examined. Remarks: Though the cause of death was revealed at the autopsy, no light was thrown upon the origin of the intestinal obstruction. If tympanitis was at any time present it was entirely obscured during the progress of the disease by the unusual thickness of the abdominal integument. The remarkable aggregations of fat may, I presume, be regarded as pathological."

Himrod's Asthma Cure.—Dr. A. J. Campbell writes in the *British Medical Journal*: "In Martindale's *Extra Pharmacopœia* there is an excellent substitute for Himrod's asthma cure, which I have tried and found very useful. Dissolve two ounces of nitrate of potassium in two ounces of boiling distilled water, and add two ounces each of lobelia, stramonium leaves, and black tea well powdered; mix well and dry thoroughly. A teaspoonful burned, and the fumes inhaled, generally gives immediate relief."

The New Antipyretics.—Of the new remedies, kairin has been little used; antipyrin was in some cases efficacious; thallin the writer has seen used in adults with varying success; but in the large majority of cases nothing reduces fever and *keeps it down* as well as the old friend quinine.—*Berlin Cor. Archives of Pediat.*

The Determination of Sex.—Carl Düsing concludes from the results of investigations made by W. Preyer and himself that in general the fructification of a young ovum with old sperm, the mother being well nourished, produces females more often than males; that the fructification of an old ovum with young sperm, the mother being somewhat badly nourished, produces males oftener than females.

A Test for Albumen in the Urine.—Dr. Kemper writes: "Take a solution of salt and vinegar in a test-tube, heat over a lamp, then overlie the solution with one drop of the suspected urine, and if albumen be present, it will plainly be seen by the appearance of a coagulum on the test solution. If no coagulum appear, albumen is not present. This test is given by Professor J. North as a modification of the acidulated brine test."

Treatment of Oxyuris Vermicularis in an Adult.—A correspondent asks for a remedy for seat worms. He has unsuccessfully used injections of quassia with santonin and castor-oil.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 27, No. 12 NEW YORK, MARCH 21, 1885 Whole No. 750

Original Articles.

REMARKS ON DIPHTHERITIC CROUP, AND THE QUESTION, "IS THE OPERATION OF TRACHEOTOMY IN DIPHTHERITIC CROUP DANGEROUS?"

BY ADOLPH RUPP, M.D.,

LATE ATTENDING PHYSICIAN TO THE NORTHERN DISPENSARY; AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I.

IN THE MEDICAL RECORD for December 13, 1884, Dr. Joseph E. Winters has published his twice publicly read and twice publicly discussed essay on the question, "Is Tracheotomy in Diphtheritic Croup Dangerous?" He concludes that the operation of tracheotomy, if performed with care, involves little if any danger to life.

Taken generally, but making due allowance for certain conditions and other not always to be foreseen eventualities, no one, I think, will combat this conclusion. But in concluding as to the dangerousness, or easiness and simplicity of this operation, these conditions and possible eventualities referred to must not be lost sight of.

Professor Winters also states that accidents during operation generally result from want of care. Also, he says, that tracheotomy never adds one element of danger to the original disease.

He asserts, furthermore, "Persistence of the original disease, delay in the performance of the operation, and neglect after, are the causes of failure."

In the consideration of these quotations from Dr. Winters' essay it should not be forgotten that they apply to tracheotomy for *diphtheritic* croup. Desault (and who not else beside) held that the simplicity with which an operation may be performed is the measure of its perfection.

Professor Winters, in the discussion following the second reading of his essay, said: "The operation should be performed by a man accustomed to sit by the bedside and watch the progress of the disease, and who therefore knows that it matters not if he complete the operation in one or twenty minutes." He also makes the statement, "Any man competent to practise medicine can, in time of emergency, without a single surgical instrument, perform tracheotomy in diphtheritic croup in a young child with a short, thick neck, with absolutely no danger to the patient." And this, he says, may be done with a pair of scissors and an ordinary penknife, and with the loss of less than a drachm of blood.'

Another statement made by him is, "When death occurs on the operating-table, the death is not due to the operation, unless performed by carelessness."

In closing the second discussion, the Professor remarked: "Regarding the entrance of blood into the trachea, there has been a great misconception concerning the performance of tracheotomy. Tracheotomy properly performed is almost bloodless."[2]

To quote another physician, who seemingly has taken sides with Dr. Winters: "It would surely be far more rational and just to temper our egotism by utilizing as guides the published experience of others, obtained from large clinical material—*plus* our own experience."[3]

[1] THE MEDICAL RECORD referred to, p. 669. [2] Ibid., p. 668.
[3] Tracheotomy in Croup and Diphtheria. Letter to the Editor of THE MEDICAL RECORD, December 20, 1884. p. 700.

Now, it is this encouragement, given by Dr. Barsch, and the hope he expresses that this question be not allowed to flag, that I, in great measure, have felt myself justified in publishing what is here written. The quoted statements from Dr. Winters' essay are based on what? He tells us upon his "impressions from reading," and secondarily, upon his "own personal experience."

Many of his statements are at variance with the reported experience of men much older and more experienced than himself, who, in learning, ability, and honesty of purpose, are, to say the least, his equals. Moreover, many of his statements not only contradict the teachings of generally accepted authorities, but are announced with that fervor and force, and formulated in such a manner as to assume the appearance of surgical dogma, and ethical judgments on those who might dare to differ with him. He being a public teacher, his assertions are all the less irresponsible. It is, therefore, very important for all of us to settle for ourselves the question which Dr. Winters has raised and answered (for himself).

Dr. Winters' essay gives evidence of wide reading by the richness of the quotations. But, after all, in this there is nothing of especial note; for it has been truly said that we all quote, and by necessity. Burke says: "He that borrows aid from an equal understanding doubles his own; he that uses that of a superior elevates his own to the station of that he contemplates." This is as significant of the proprieties as of the propriety of quotation. Respecting quotations for scientific purposes, the rule followed by Robert Boyle is even now a very good one, namely, to appeal to authors rather as witnesses than as judges.

Extensive reading and the ability to quote largely do not invest one with the right of laying down the law for others. Reading has been called thinking by proxy. Perhaps it was for reasons of this kind that Sir Astley Cooper advised students not to read much. He who would act for himself must think for himself. This is character. Who would presume so much as to ask others to have their thinking done for them, yet continue responsible for their acts? The thinkers were irresponsible tyrants; the actors, the workers, fools. Still, however independent we may presume to be, we go very willingly for help when we feel that we need it.

In illustration of the importance of what has been said of thinking for one's self, I shall quote Professor Schüller on tracheotomy, which operation, according to Dr. Winters' asseverations, is such an easy and simple one. In his work on "Tracheotomy," etc., Professor Schüller writes essentially as follows: "Unfortunately, widespread is the notion that venous hemorrhage especially is matter of no serious concern in tracheotomy; it is thought that this bleeding *must* stop as soon as the windpipe is opened, and the patient given a chance to breathe. However, in cases of laryngeal obstruction, the patient will not always breathe the instant the trachea is opened, and thus sufficient time will elapse for blood enough to enter the windpipe, and to make a desperate case a hopeless one. And," continues Professor Schüller, "no more deplorable and dangerous superstition has gained credence than that tracheotomy is always easily performed on the child, be the hemorrhage profuse or little." For the spread of this superstition, the Professor goes on to say, inferior surgical text-books and surgical ignoramuses are to blame, individuals who have done one or two operations or none at all, but who with facile grace have writ-

ten up this chapter of operative surgery at their writing-tables. Children, according to Schüller, who have died from suffocation caused by blood flowing into the trachea through a tracheotomy wound, are not so few as the records in the literature of this operation might lead one to suppose; for it is quite natural for operators to keep such instances from gaining publicity.

These words of Professor Schüller's are in the main opinion, but opinion not without very good foundation, as shall be seen further on. However, it is by demonstration rather than by reasoning alone, however sound, or by the expression of opinion, however well founded, apparently, that the harmlessness or danger of this operation in diphtheritic croup can be established. The quotations from Schüller prove this much, that the question raised by Professor Winters is answered every bit as forcibly in the affirmative as has been negatively done by himself.

II.

What Froude says in reference to the historian in general I would apply to the historian of tracheotomy. Froude says: "History itself depends on exact knowledge on the same minute, impartial, discriminating observation and analysis of particulars, which is equally the basis of science." Further: "The business of the historian is not with immediate realities which he can see and handle, but with the combinations of reality and human thought, which it is his business to analyze and separate into their component parts."[1]

I am merely offering remarks, and shall not be required to furnish a history of this operation. Dr. Winters deprecates the age in which he moves and has his being by rounding off his remarkable essay with a quotation from Professor Letamendi, who says: "In the days of more knowledge, and less nonsense, tracheotomy will be ranked among the minor surgical operations." In his historical survey of the opinions entertained regarding this operation, Dr. Winters begins by saying that the "older authors always spoke from the force of their convictions in definite, unmistakable terms." He cannot mean only those authors who speak so favorably for the thesis he is advocating, for he quotes the older authors of both sides of the question. Medicine, in ages so far away from us as those in which Asclepiades, Ætius, and Antyllus flourished, is somewhat enigmatical to most of us, because we can find out so little about them and their thought that is practically worth knowing and thinking about. It is evident that practitioners are not the worse off practically for living and working in ignorance of these once eminent men.

Adams[2] writes that Ætius makes mention of tracheotomy in such terms as prove that it must have been done in his time, at least occasionally. He did not approve of this operation; not in cases of angina is sure. We may fairly assume that Ætius did not disapprove of this operation, because he knew nothing about it.

Although Cælius Aurelianus is reported as telling us that Asclepiades saved many lives by tracheotomy, he himself had not enough faith in the operation to think it well to advocate it as a safe, easy, and harmless remedy.

More than fifteen hundred years ago, Antyllus is credited with having revived this operation. And of him Adams says: "Of all the Greek writers, Antyllus is the only one who has left a description of this operation." And his description is very far from being that described as being the proper conception of the operation. Antyllus cut across the throat—transversely—and in the region of the third or fourth cartilaginous rings of the windpipe, and then between these, transversely across, into the lumen of the trachea. He chose this part of the throat in order to avoid as much hemorrhage as possible. But Antyllus approved of the operation only "in inflammations about the mouth and palate, and in cases of indurated tonsils. . . ." He held that it was of no avail to operate "when all the arteries (the whole of the trachea?) and lungs are affected" (Paulus Ægineta—by Adams). If Paulus Ægineta operated, he probably followed Antyllus.

After Paul, in the history of medicine, as it is generally written, came the Arabian doctors, who, it is said, knew more of, than the operation practically.

In medical history the advances go by centuries.

In the sixteenth century we find Fabricius ab Aquependente, whom Dr. Winters quotes as saying, "The operation is absolutely free from danger; . . . there is no part of the least consequence exposed to injury in this operation." After having been performed for more than one thousand years according to the method of Antyllus, this Fabricius has thoughts of improving on that method, and he sets about to realize his cogitations. Fabricius makes his cut *over* the trachea *longitudinally*, and why? To avoid the dangers incident to the operation as done by Antyllus. Fabricius would avoid cutting across blood-vessels and muscles. Thus a step toward the simplification of this operation and its proper conception was attained. He, however, cut between the rings (third and fourth) transversely into the trachea. Fabricius introduced the canula.

In the seventeenth century one Habicot, of Paris, advocated tracheotomy for severe inflammatory conditions of the trachea; and about the same time Severinus, Professor of Surgery at Naples, advocated and lauded the excellent results it afforded in the treatment of croup.

Not only in France and Italy, but also in Germany the operation was now utilized as a remedy for what seems to have been croup or diphtheria.

In the latter part of the seventeenth century, "Dekkar proposed to perform the operation with a cutting canula;" and why? Can any other answer be given in justification of this proposal than that Dekkar thereby meant a simplification of the operation, a diminution of its risks, as well as expedition in its performance? Since Dekkar's time many and various tracheotomes have been devised by eminent surgeons, but these instruments have never become popular.

In the early part of the eighteenth century, Heister made the next tangible advance in the thought of this operation. He demonstrated that wounded cartilage heals, and the fear of cutting through the tracheal rings ceased to plague surgeons, and the incision was made through the rings—and the whole operation was done longitudinally to the long axis of the trachea. Vast improvements these in the methods of the ancients! Improvements needing much more than a thousand years for their consummation. And yet this operation is called a simple, an easy one; and the "older authors," who are so much in the clouds, as far as we are concerned, are dragged into our midst to bear witness against themselves.

Whatever may have been the opinion of individual surgeons as to the non-dangerous character of this operation, general opinion evidently was against considering it an easy affair. Even those quoted as considering it an easy operation, certainly did their best to make it so, and subtract from its risks and dangers by their innovations. This, it seems to me, the history of this operation, or as much as we can get of it, demonstrates clearly enough.

In our own century the improvements concerning this operation have not been few, but rather of detail than principle. The operation has been more variously applied, its indications better founded, and its therapeutic value more correctly and soberly estimated. For all these later improvements we are greatly indebted to the French, who not only pointed out, but most courageously pushed on the way to their achievement.

To avoid the profuse hemorrhage sometimes attendant on this operation in some localities, the galvano-cautery

[1] Scientific Method Applied to History. Short Studies, etc., vol. ii.
[2] Paulus Ægineta, vol. ii., pp. 301–303.

has been proposed and used, and, I believe, first by Professor Bruns, of Tübingen.[1]

III.

"True medicine," says the wise Sydenham, "consists in the discovery of the real indications rather than in the excogitation of remedies. Those who have neglected this have put arms into the hands of the empiric, and taught him to imitate the physician." So, from even a rapid glance at the history of tracheotomy it may be seen the "older authors thought and taught." And so, too, those who will take the trouble to carefully read the literature of this operation with reference to croup, and diphtheritic croup in recent times and our own, will not fail to find that men in these "ignorant and nonsensical times" have not ceased to think and teach. Quite *à propos*, in connection with this question, is the remark made by Professor Moxon in his eulogy on Professor Fagg: "In much of our treatment, no doubt, the idea of the remedy is inserted into the idea of the disease when nothing really exists corresponding to the ideas with which we suppose ourselves to be acting."[2]

Now, how do the ideas of tracheotomy and diphtheritic croup correspond?

Diphtheria is a constitutional disease, probably primarily local in character. Its severity is not proportional to the faucial or visible exudation. There may be a good deal of faucial and pharyngeal exudation, with moderate constitutional disturbance. There may be great constitutional disturbance, possibly eventuating in death, and little or no discoverable exudation in the mouth, fauces, pharynx, or nose. Neither is the severity of the sequelæ proportioned to the amount of exudation. Death may result from heart-failure, respiratory failure apart from laryngeal stenosis, deglutitional failure, renal complications, and even by ear and brain complications, etc. It is usually a short-time disease, that is, limited; but irregular and treacherous in its phenomena. The complexion of the disease varies with the epidemic, so, too, its severity. Laryngeal stenosis or croup as a complication is commoner in some epidemics than during others, and at times may rarely occur, or not at all.

In his first experience with the disease, Dr. Ripley[3] rarely met with a croup complication.

When death by laryngeal stenosis threatens, in diphtheria, tracheotomy is the one remedy, of many recommended, which is more certain of prolonging life long enough for giving the patient a chance for outliving the disease, and escaping impending suffocation.

Dr. Ripley, whose experience in the treatment of this disease is a large one, and who is a careful observer, with nothing of cheap sentimentalism about him, says: "Thus far in the history of the treatment of croup tracheotomy has done more in saving life than all other means combined."[4]

Professor Jacobi says: "Diphtheria of the larynx, whether it be of primary origin or the result of extension from the fauces, is nearly always fatal. In severe epidemics the mortality is ninety-five per cent. Tracheotomy, too, saves but few of those who take the disease at such a time. In fifty consecutive tracheotomies, from 1872 to 1874, I did not see one recovery. In the last few years I have seen few good results. In average epidemics, tracheotomy will save twenty per cent."[5]

This statement is praiseworthy, because it is so honest; but, though rather of gloomy portent regarding the operation, it is not meant to, nor does it prove, the inutility of tracheotomy even when epidemics are severe.

Dr. Ripley says: "If diphtheritic deposit on the fauces or in the nasal passages have preceded the onset of the croup for a number of days I consider it a favorable circumstance." He gives in proof of this statement the following interesting statistics: "In 70 of my own operations, in which I have carefully noted whether the croup were primary or occurred secondarily after several days' illness from nasal or pharyngeal diphtheria or one of the eruptive diseases, the proportion of recoveries in 25 cases of late croup was forty per cent.; in primary croup, twenty-four per cent.

Krönlein[1] found that when the diphtheritic exudative process remained stationary in the fauces, pharynx, and nose, the mortality of the disease was thirty per cent.; but when this exudative process extended down into the larynx and trachea, though the cases were tracheotomized, the mortality ascended to over seventy-three per cent.

Besides the peculiarities of epidemics, and of the pathological process, the age of the patient operated upon very materially influenced the percentage of recoveries after tracheotomy.

Krönlein found that the younger the patient the less are the chances of recovery. The percentage of recoveries improves up to the eighth year of life, and from this to fourteen years of age remains about the same. Of fifteen children tracheotomized in the first year of life, only one recovery is noted. Of five children tracheotomized during the twelfth year of life three recovered.

The statistics of cases done in private practice are said to be better than those of hospital practice. This may be so in some kinds of private practice; but the private practice among our tenement population would probably not offer better tracheotomy statistics than the hospitals do, and I doubt if they would be as good.

Dr. Winters, in one of his conclusions in his essay, says: "Performed early, it (tracheotomy) snatches from certain death fully two-fifths of all cases." No other warranty for the infallibility of this conclusion is given than its mere assertion.

When men, whom we know to be as experienced as Dr. Jacobi and Dr. Ripley are, give us demonstrations of fact rather than bald assertion, how can it be fairly expected that we shall allow ourselves to be influenced by such a conclusion as Dr. Winters has offered?

Lindner[2] says: "Of 101 tracheotomized patients 63 died, or about sixty-three per cent.; 38 recovered, or about thirty-seven per cent. At a first glance these figures look very well, better than many a larger array of figures; but these calculations are worth about as much as the calculations based on larger statistics, until now published, namely, of no value at all." They are of no value when the circumstances peculiar to each case operated are left out of account. Statistics are not tables of absolute facts and truths; but rather indices of these. Neither can statistics be justly used in passing judgment on the fortunes of practice. Practice consists in the treatment of single cases, and the physician or surgeon is not privileged to pick his cases by rule of statistics. Thus Dr. S. S. Jones, of this city, has the courage to let us know that he has had only one successful tracheotomy in seven. Krönlein instances the case of a Berlin surgeon, who tracheotomized sixteen times before he could record one recovery. And I have already quoted Jacobi's statement of fifty consecutive tracheotomies without one recovery.

Krönlein, in his splendid essay on this subject, already quoted from, gives encouraging proof, in various shapes, of the utility of this operation in overcoming the laryngeal stenosis at times incidental to diphtheria. What can be more convincing in this respect than that of twenty-two children tracheotomized, though in a state of asphyxia, and yet two of these brought back to life by means of the operation! One child was two years and eleven months old; the other three years and three months. The asphyxia had been caused by diphtheritic laryngeal stenosis.

Professor Jacobi[3] tells us that "the diphtheritic exu-

dative process which ascends into the larynx from the trachea is absolutely fatal. In these cases tracheotomy postpones the fatal issue only for a few hours." I have heard other experienced physicians express a similar opinion. These men have seen much of diphtheria during the last thirty years. But Dr. Winters' experience must have been different from theirs, for he boldly tells us: "When the disease involves the trachea, it is *by propagation from the larynx, and not by a simultaneous attack* on the larynx, trachea, and *bronchi*. In many cases this *extension downward may* be prevented by early making a way for sublaryngeal respiration, so that the inflamed larynx may be allowed to rest, and be saved from irritation by the passing breath, and thus cause arrest of the diseased action there." Except the mere assertion no proof is given for it, which I suppose we are to infer rests on his experience. He also assures us that this diphtheritic exudative process goes beyond the larynx less frequently than many of us suppose, and in confirmation of this we are told that Krönlein found it only forty-six times in two hundred post-mortem examinations extend beyond the limits of the larynx.

Dr. Henry Wm. Fuller, in his essay on "Tracheotomy in Croup,"[1] tells us: "With the view of determining the existence, seat, and extent of false membranes in the air-passages, M. Chanantais has reported the post-mortem appearances observed in one hundred and forty cases of croup. They occurred in France, and therefore the majority of them were probably examples of the diphtheritic form of the disease:

In 25 no false membrane beyond the larynx and middle of the trachea.

In 50 the affection reached the lower part of the trachea.

In 22 the larger bronchi were affected.

In 19 the false membrane reached the smaller bronchial ramifications.

In 7 the seat of exudation was not precisely limited.

In 7 no false membrane was found in the air-passages.[2]

Another series of 171 cases has been collected and reported by M. Hussenot.[3]

In 30 the larynx and trachea implicated; condition of bronchi not mentioned.

In 78 the false membrane in the trachea, but not below.

In 26 the larger bronchi affected.

In 16 the smaller bronchi implicated.

In 21 no false membranes found.

If these figures did not disprove Dr. Winters' assertion, they would at least prove that trusting to one set of figures is apt to lead us into a fallacious course of reasoning.

With reference to Krönlein's cases it is plain that Dr. Winters has stated only so much concerning them as his argument needed for appearances of validity. Krönlein,[4] in the table in which these forty-six cases are mentioned, states that they were cases of laryngo-tracheal diphtheria, without any discoverable accompanying exudation in the throat or nose. As to whether or no the early performance of tracheotomy is capable of preventing the descent of the exudative process into the lower air-passages, Dr. Winters is himself really not so sure about it as at a first glance seems. He merely says this progress *may*, *not that it is*, prevented. He does not tell us in how many, nor in which cases this *may* occur. His arguments of rest to the larynx as a preventive of the spread of the exudative process are only analogical in character. Syphilitic and tubercular ulcerations and other chronic laryngeal troubles have nothing pathogenetically in common with the diphtheric process.

In the discussion following the second reading of his paper Dr. Winters said: "With reference to the extension of diphtheria to the bronchi, if diphtheria extended into the bronchi it almost always did so before the performance of tracheotomy. Dr. Winters did not think that a post-mortem record could be found which would tend to show that the membranous exudation of diphtheria appeared in the trachea and bronchi *after* the performance of tracheotomy when it did not exist previous to the operation. The extension of the disease was by its propagation downward, and in those cases in which it was found death occurred within a comparatively short period, before sufficient time had elapsed for the disease to extend there after the performance of the operation."

In the "Transactions of the Medico-Chirurgical Society" for the year 1857, vol. xl., Dr. Henry William Fuller reports the following case: A boy, four and a half years of age, was admitted into the hospital under the care of Dr. Wilson. The child had had scarlet fever six weeks before the present illness of croup set in. As the child had been barely twelve hours under treatment, and the dyspnœa, though considerable, was not accompanied by any great degree of pallor or lividity of countenance, it was judged expedient, for a time at least, to continue the administration of calomel and salines, and tartar emetic in one-fourth grain doses. The child slept at intervals during the night, and though he suffered one or two attacks of urgent dyspnœa, he appeared somewhat easier the next morning. Toward noon, however, the symptoms assumed an alarming character, and in a short time the countenance became ghastly pale, and suffocation became imminent. Mr. Hewitt was therefore asked to perform tracheotomy, which he did at 1 P.M.; and the operation was not attended by much hemorrhage. The child was a good deal exhausted, but at 2 P.M., after coughing up a considerable quantity of mucus, no false membrane, through the wound, he was greatly relieved and fell asleep. Beef-tea, and port wine in half-ounce doses, and cinchona were ordered. Throughout the remainder of the day and the following night he seemed comfortable in every respect; he continued at intervals to cough up through the tube a considerable quantity of mucus, and each time he did so he manifestly obtained relief; during the intervals the breathing, though quicker than natural, was performed without difficulty.

Early on the morning of the next day his face became flushed, his skin hot, and by degrees some difficulty of breathing ensued. From this time the dyspnœa gradually increased, and at half-past two in the afternoon became urgent: no mucus or discharge of any kind came through the tube, which was removed without effect, and death from suffocation speedily took place. Dissection showed the subcutaneous tissue round the tracheal opening infiltrated here and there with purulent fluid; the pharynx exceedingly congested; the tonsils enlarged and hardened, and presenting old cicatrices, and one or two small specks of recent ulceration on their surface; the epiglottis natural, but the larynx and trachea almost down to the bifurcation lined with concrete albuminous exudation, which at the upper part of the windpipe was exceedingly firm, forming a cast of the tube; the bronchial lining membrane congested, and covered with thick mucus, and the right lung in one part passing into the early stage of red hepatization. The other viscera were healthy.

Whether Dr. Winters and those who side with him would accept this as an instance of the extension of the exudative process down the trachea *after* the performance of tracheotomy, it is not easy to say. Except the chronological test, Dr. Winters does not furnish us with any clinical test which might convince him of the existence of such recorded cases as he has doubts about. In commenting on this case Fuller calls attention to "the immense relief obtained by the operation, and the presumption thereby afforded that at the time of its performance the tracheal and pulmonary obstruction was far less extensive than that found after death, and the length of time during which the patient continued free from

urgent dyspnœa . . ." It is difficult, before operating, to ascertain how much, or if any, of the trachea is involved in the diphtheritic process, when the laryngeal stenosis has become such as to demand an operation.

In a number of cases of diphtheritic croup analyzed by Krönlein, inspection failed to discover any exudation on the palate, fauces, or visible pharynx, although swelling and redness of these parts were present; and in not a few of these cases diphtheritic exudation appeared on these parts later on, where none had been before.

Mr. Marsh, in his paper quoted from by Dr. Winters, narrates the following case: "A girl, four and a half years of age was attacked with laryngeal diphtheria on January 26th. On the morning of the 27th the difficulty of breathing had become so great that Mr. Paget recommended and performed tracheotomy. She had immediate relief from her dyspnœa, and except that she had some albumen in her urine, she progressed favorably. On plugging the orifice of the tube on January 30th, it was found that she could speak, though indistinctly, and breathe imperfectly through the larynx. On the 31st the tube was corked, but she could not then breathe sufficiently, and the cork was removed. Next day the canula was corked again, but the larynx still remained almost completely obstructed. On the ninth day after the operation, false membrane was seen upon the fauces, and the child coughed out shreds of exudation through the canula. So it seemed evident that diphtheria, accompanied with exudation, had continued after the operation, and that the larynx had been, and still was, occupied by the deposit. There were no means of ascertaining before that this was the state of things—the throat had been examined but nothing had been detected, no membrane had been coughed up, and the child's general condition was not such as to suggest still active disease. The albumen had disappeared from the urine, and she had very little fever." [1]

In THE MEDICAL RECORD for July 17, 1880, Dr. Ripley narrates an interesting case, which clinically may be taken as an instance of the progression of the diphtheritic process after operation. The case was a boy, two and a half years of age, who was taken sick on January 4th. On January 5th and 6th he had suffocative attacks, each lasting several minutes, and in the evening of the latter day dyspnœa slowly developed, and the breathing had become noisy and the voice hoarse. At 8 A.M. on the 7th of January, Dr. Ripley saw the child for the first time and found "the patient in an extreme condition; the dyspnœa was painful to witness; the face was pallid and covered with a cold sweat; the eyes partly closed, and the sclerotic of a bluish color; the extremities cold, and the senses blunted. Both nares plugged with mucus. The respiration, carried on through the open mouth, 40 per minute; temperature 97.1°. The lungs generally tympanitic on percussion, while on auscultation little could be heard except the sounds conveyed from the larynx. No membrane was seen in the throat or nose. The tonsils were large and congested, and the neck appeared a little swollen. The operation of tracheotomy was simple and bloodless. Although the trachea contained a large amount of puriform matter, no membrane could be found. The operation gave complete relief, the respiration falling from 40 to 28 per minute. At 10 P.M. the respirations were 26, the breathing noiseless. Secretion from the tube moderate.

"January 8th, 10 A.M.—A fair night was passed, and child looking well. Free purulent discharge from the nostrils, and membrane seen lining the left; but still none in the throat. By pouring a teaspoonful of warm water into the trachea coughing was excited, and large shreds of false membrane were expelled. The breathing had been harsh, now the breathing was easy. Pulse, 140; respiration, 38; temperature, 100°.8. At 7 P.M. breathing harsh. The condition now became worse in all respects. On January 11th—the fifth day after the operation—signs of exhaustion appeared; respiration had become labored and sawing. Temperature, 105°; respiration, 44; pulse, 160; and on January 12th the boy died, the sixth day after operation. The post-mortem examination was made eight hours after death, in the presence of competent witnesses. On removing the sternum the lungs were found hyperinflated and bloodless, and they did not collapse. Patches and streaks of collapse were found, particularly in the right upper lobes, but in the left also, and posteriorly. A shred of membrane was hanging into the tube from the left vocal cord; lining membrane of the trachea congested. In the right lung the false membrane extended into the sixth division; in the left into the fourth bronchial division. Wherever membrane was found it was for the most part loosely attached and the mucous membrane underneath congested. There was very little purulent matter in the smaller bronchial ramifications" (pp. 58, 59). Now, Passavant admits that when tracheotomy is performed early the diphtheritic exudative process continues and progresses, and he pleads that the blame ought not to be cast on the early performance of the operation. Of course not.

The membrane may persist in remaining in the larynx for more than several days. Mr. Marsh, in his paper already quoted from, reports the following case: "A patient in the Hospital for Sick Children, who had suffered tracheotomy for diphtheria, died of pneumonia fourteen days after the operation. When the larynx was examined it was found completely blocked by thick, false membrane, which extended downward nearly to the bifurcation of the trachea."

Bearing these facts and cases in mind, comment on the above-quoted statements of Dr. Winters becomes unnecessary.

Although the assertions as to tracheotomy possibly or probably checking the progression of the diphtheritic process have scarcely any better foundation than the mere saying so, the operation is none the less a needed and beneficent therapeutic resource in cases of continued and progressive laryngeal stenosis, even so badly conditioned as are these of diphtheria. However, it is not wise, nor is it just, to claim too much, even for tracheotomy, in diphtheritic croup. It has often been said that simplicity is the index of truth. Nothing could be simpler than Dr. Winters' summary of the pulmonary changes resulting from laryngeal stenosis in diphtheria in cases not operated, in cases operated "late," and in cases operated "early." In cases of diphtheritic croup where tracheotomy has not been done, says Dr. Winters, post-mortem examination reveals the lungs and bronchi congested, and "always an excessive quantity of mucus on the bronchial mucous membrane. In a smaller number of cases, œdema of the lungs and pneumonic changes." When cases of "late tracheotomy die soon after" (how soon not stated) "the post-mortem changes are much the same as in cases not operated on." And lastly, "when death has taken place from several days to two or three weeks after the operation, the mucous membrane of the bronchi and pulmonary vessels is quite normal." [1]

These formulas, we are told, are based on an examination "of a large number of autopsies" which had been carefully recorded; and that his "own records" invariably give the same showing. In organizing his facts into these three formulas the perfection of that art has been attained which Lord Bacon says has for its object the perfecting of nature. No one will object to the union of facts into generalizations, for doing that is organizing knowledge, making facts the easier to comprehend, and knowledge all the more useful. But in organizing knowledge the facts must not be hidden from us, nor the

[1] St. Barth. Hosp. Reports, vol. iii., p. 327.

[1] THE MEDICAL RECORD, December 13, 1884, p. 650.

sources whence they are derived. A theory may be correct enough, but the facts may be false, or wrongly applied. Bretonneau, whom Dr. Winters praises so highly as an observer, in which praise all who have read any of Bretonneau's works will join him, describes the post-mortem appearances of a non-tracheotomized case of croup thus: "Lungs crepitant, of a rosy white, the tint of which became more deep toward the posterior and dependent parts. The mucous membrane of the bronchial tubes was pale, and the first traces of the disease were observed only in the trachea. Toward the middle part we began to discover some violet-colored spots, not very distinct, but which were found more confluent and of a more decidedly red color on tracing this tube upward. The diphtheritic membrane almost entirely obliterated the glottis." This child was five years old, and had frequently suffered during the last two years of life from coryza and bronchial catarrhs. The croup had been treated by applying twenty-two leeches at two intervals, and the blood had flowed abundantly for twelve hours. Two pounds of the syrup of ipecac with tartar emetic had been given within three days' time. There had been repeated vomiting.

On the sixth day calomel and mercurial inunctions had been resorted to. Oxygen gas had also been given, and "the livid tint of the lips and face, for an instant, changed to red, the stupor was sensibly diminished, and perhaps under more favorable circumstances the treatment might not have been unavailing." Just so; that's what is so often needed to make the treatment successful, but is often wanting—these "more favorable circumstances." Bretonneau reports this case as an instance of the failure of blood-letting in the treatment of croup. The therapeutics no doubt influenced post mortem appearances. General anæmia had been produced. But the lungs showed active hyperæmia, passive congestion, also anæmia, and emphysema.[1] In the autopsy of Case VII.—also detailed in this Second Memoir—the pulmonary changes were "two rather circumscribed and partial spots of hepatization, which were observed toward the centre of the right lung, made us suspect that the inhalation of hydrochloric vapor might have caused inflammation of the pulmonary parenchyma;" and further on Bretonneau says, "the mucous membrane of the bronchi was in a healthy state, or not much different from it."

Dr. Barker (London), in the thirty-eighth vol. of the Med.-Chirurg. Soc. Trans., relates the history of a case which will not accommodate itself to the three formulas of pulmonary changes induced by laryngeal stenosis as fashioned by Dr. Winters. It was that of a child, seven and a half years of age, in whom post-mortem was found an intralaryngeal growth almost occluding the glottis. When the child was brought into the hospital, its mother stated that he had always been croupy. The laryngeal growth had been developing a long while, no doubt. Dr. Barker writes, that it is "difficult to convey by means of words the symptoms that were present," when he first saw the child, so distressing were they. The child died asphyxiated, presenting the symptoms of croup. Post-mortem examination revealed: "The bronchial tubes and trachea contained a good deal of frothy mucus, but in other respects they and the lungs were healthy." This case had not been tracheotomized. Though not a case of diphtheritic croup, it is quoted as illustrating the influence of laryngeal stenosis on pulmonary conditions as judged of by post-mortem appearances.

Dr. Fuller, says: "Not only is it not uncommon to find pulmonary engorgement in croup unconnected with any material obstruction of the upper air-passages, but in many instances, even when the larynx and trachea have been plugged with false membrane, the amount of pulmonary engorgement observed after death has not been greater than that which occurs in the course of three minutes in cases of ordinary asphyxia." The principal pulmonary changes found by Passavant, in his examinations of children that died in consequence of diphtheritic croup, were pulmonary emphysema and anæmia in front, and especially above, and congestion of the lungs, especially posteriorly, inferiorly. Passavant opines that this congestion of the posterior inferior portions of the lungs should not be attributed to hypostasis, because, he avers, if the corpse be placed on the belly soon after death, instead of being allowed to lie on the back as is usual, it will be found that though the anterior portions of the lungs are now somewhat more vascular, the vascularity of the posterior portions is still greatly in excess. This manœuvre, however, does not do away with the difficulty encountered in not believing the posterior congestion to be due to hypostasis. Could the child lie on its belly as long as it must on its back before it dies, would not this "passive" congestion be as common anteriorly as he found it posteriorly? I think so.

Mr. Thomas Bryant's case of foreign body in the larynx, though "showing how quickly obstruction to the respiration may induce changes in the bronchi," does not, in my opinion, go to prove what Dr. Winters seems to assume it does. Post-mortem examination, we are emphatically told, showed that where the bronchi were completely obstructed the portions of lungs to which they led were *airless*.

Laryngeal obstruction from the diphtheritic process, and when due to a foreign body, very often differ in kind as well as in degree. From all that has been passed in review, concerning the pulmonary changes incident to laryngeal stenosis peculiar to diphtheritic croup, it will have been seen, rather corroborates what Dr. Ripley has been teaching us that his post-mortem examinations reveal.[1]

(To be continued.)

[1] Case IX., pp. 49-54, Bretonneau's Mem., Second Mem., New Syd. Soc. Ed.

[1] In this section I have made mention of only or mainly the principal pulmonary changes induced by laryngeal stenosis to the degree inconsistent with life. Passavant, Ripley, and others mention other changes too, but they are minor to these. I have not attempted an explanation of pulmonary changes due to diphtheria, etc.

THE CURE OF HERNIA IN THE INFANT.

By W. B. De GARMO, M.D.,

INSTRUCTOR IN THE NEW YORK POLYCLINIC.

In reference to hernia as we find it in the adult, it is impossible to speak with any degree of certainty respecting its cure. This fact has long been established, and is very generally understood, so well understood as to lead in many instances to the neglect of suitable treatment for its relief, the patient being assured that nothing can be done, and that he must get along as best he can.

That very many practitioners do not discriminate between hernia as seen in the adult and that occurring in infancy, I have had frequent evidence of, and that such an error is productive of great harm there can be no question in the minds of those who have had any amount of experience in the treatment of cases of this class.

It is an error to assume that nothing can be done to relieve the adult sufferer from hernia, and it is a still greater error to assume that hernia in the infant cannot be cured. Careful, early, and persistent treatment will be rewarded in almost every instance by the cure of the case, and the child saved much subsequent trouble and suffering.

This result cannot be attained by recommending the use of an appliance, no matter how perfect it may be, and leaving the case without further attention, for while we have, as I believe, nature on the side of cure, she requires the intelligent aid of the physician, and that aid should extend over a sufficient period of time to insure the cure of the case.

It is not necessary to enumerate all of the causes of infantile hernia in this brief paper, but I wish to make special mention of two or three, as unless these are

recognized and removed, success will not be likely to attend its treatment.

Phimosis is not only a more frequent cause of hernia than is generally supposed, but its presence is an almost insurmountable obstacle to the cure of the case. When it is discovered that the infant has an abnormally long prepuce, with a contracted orifice (the inner surface of which becomes so agglutinated between each urination that this act is only accomplished by straining), then it is highly important that this difficulty should be removed at the outset. This done, an existing hernia will yield readily to treatment, and a cure result in due time.

Not infrequently constipation is the cause of hernia in infancy, and inquiry should always be made on this point.

Another cause, which I have found in several cases, is the customary habit of tight bandaging; some nurses being accustomed to tightly bandaging the child as well as the mother. This forces the viscera into the lower part of the abdominal cavity, and produces undue pressure upon this region. In many instances I have found it necessary to insist upon the loosening of these belly-bands in order to secure favorable conditions for the retention and ultimate cure of the hernia.

In view of the fact that these and many others are avoidable causes, or causes that may be readily removed, it is not best to look upon any case of hernia as having its origin in a so-called inherent defect in the physical organization of the individual. To make a diagnosis of hernia, with no attempt to go farther, is, I regret to say, a practise as common as it is superficial, and the importance of a change in this respect will be quickly demonstrated to any physician who will adopt the more thorough method of examination.

It has been asserted by some writers that congenital hernia is by its very nature incurable; this, in the light of repeated experience, should be looked upon as wholly incorrect. Individual experience leads me to consider this class of cases nearly, if not quite, as curable as non-congenital hernia. It is simply the result of delay in the division of the tunica vaginalis from the peritoneum; that this division can take place after as well as before birth is reasonable, provided proper aid is rendered to prevent a mechanical obstruction to that occurrence.

Nature unaided, however, cannot complete this change so readily, as from the altered conditions and position of the child there is a more or less constant protrusion through this opening. If this protruding mass is returned within the abdomen, and its complete and constant retention accomplished by the judicious application of pressure over the canal, the cure can be obtained nearly if not quite as quickly as in any other form of hernia.

In congenital hernia there is one complication occasionally met with, with which it is best to be familiar, as if not understood it makes treatment difficult and perplexing. I refer to the presence of fluid within the abdominal cavity, which descends into the scrotum with the hernial contents. In quantity it may amount to one, two, or three ounces; it usually returns when the hernia is reduced, but cannot be retained within the abdominal cavity by any appliance that can be tolerated by the infant, and within a short period of time after the truss has been applied it will be found again in the scrotum.

So far as my observation goes it has not been necessary to adopt any special treatment in these cases; usually a properly fitted truss with a small convex pad will retain the intestine, and the fluid will, ordinarily, disappear within the first month or two. Such cases are quite likely to be neglected, or treatment abandoned under the supposition that nothing is being accomplished, that the hernia is not retained, if their true condition is not recognized by the physician and made known by him to the parents.

Hydrocele is a frequent complication of hernia in infancy, and several cases have come under the writer's observation wherein it seemed to have been produced by neglecting the hernia; usually, tapping has been sufficient to produce a cure, but in some it may be necessary to resort to one of the well-known operations for its radical cure; if of any size it certainly should not be allowed to remain, as its presence materially interferes with the treatment of the hernia.

While strangulated hernia is, in the infant, exceedingly rare, and very few reported cases are on record, I have seen several cases wherein the reduction of the hernia was attended with great difficulty—in fact, in one instance, impossible until an anæsthetic had been administered.

"At how early an age is it proper to begin the treatment of hernia?" is a question that has been repeatedly asked the writer by physicians. There appears to be almost universal doubt in the professional mind on this point, and many practitioners feel that they are giving the patient the "benefit of the doubt," by advising delay of treatment until the child reaches an age of one, two, or three years. Experience proves conclusively that advice of this character is erroneous, resulting only in diminished chances of cure, increased difficulty in treatment, and adding to the discomfort of the child.

The writer has frequently begun treatment on infants two weeks old, and in one instance on a child one week old who was the unfortunate possessor of two inguinal and an umbilical hernia. One month should certainly be the limit as to the length of time that should be allowed to elapse before treatment is commenced.

Intestinal irritation appears very commonly in infants afflicted with hernia, and as commonly disappears when the hernia is properly retained; in children previously restless and troublesome, immediate improvement may frequently be noticed. I wish to call especial attention to this fact, as I have seen the treatment of hernia postponed on account of intestinal disturbance being present. A carefully adjusted truss does not seem to inconvenience the most delicate child; on the contrary, it seems in almost every instance to afford some relief in the class of cases just mentioned.

As to the best truss for use on infants, I believe that the experience of any impartial observer will lead him to confirm my own conclusion, that the only one perfectly adapted for such use is the hard-rubber truss; I can hardly conceive of any substance which would be so well tolerated by the infant skin. Springs protected by this substance retain their elasticity, do not corrode by their necessarily frequent wettings, and the entire truss can be washed daily. With no other appliance known to me can such strict cleanliness be observed.

The best style of spring for single hernia is that which crosses the front of the abdomen and passes around the hip opposite to the affected side. In very young children in whom double hernia exists, I am in the habit of using this same style of truss, with another pad arranged to slip on the spring, *i.e.*, having one pad on the end of the spring and the other about two and a half inches from the end. This will be found better for use on children where the pelvic measure is less than twenty inches, than the double truss as ordinarily manufactured. In those measuring more, and in adults, this method of fixing both hernial pads to the one spring is not advisable.

It will rarely be found necessary to use anything but the small oval pad, which should always be located as nearly over the internal ring as possible; much harm may result from the application of a small prominent pad over the external ring, into which it wedges itself and thereby increases the difficulty instead of aiding in a cure.

The spring should be long enough to extend well around the back, and the pressure very carefully regulated to meet the requirements of the case in hand. The use of the diagram method recommended in THE MEDICAL RECORD of June 21st[1] will be found a great aid in securing an accurate fit.

[1] The Practical Treatment of Abdominal Hernia: MEDICAL RECORD, June 21st, 1884.

In using truss springs covered with hard rubber it must be borne in mind that they should be thoroughly warmed by passing through a gas or lamp flame before attempting to shape them, when well warmed, however, they may be bent to any desired form, and the pressure increased or diminished at will.

As the child grows and changes in shape, a corresponding change must be made in the shape of the truss, and the pressure of the spring must be decreased as the hernia improves; for these reasons the case should be seen every week at first, and should be kept under observation for at least six months. Under the most favorable circumstances the truss should be worn day and night for one year. It should be removed and washed every time the child is bathed, care being taken to prevent the descent of the hernia at such times. Absolute cleanliness must be insisted upon to guard against excoriation of the surface.

Those forms of truss which are applied from the affected side, with the pad attached to a curved descending arm commonly known as the "French," "German," "Chase" truss, etc., are entirely unfit for use upon infants.

Respecting cure by surgical procedure it is perhaps sufficient to say that operations upon infants and in early childhood for so-called radical cures are entirely unjustifiable. Fully ninety-nine per cent. of such cases can be cured by milder means, and it is questionable whether the remaining one per cent. would secure a like result by surgical aid.

THE DETECTION OF ONE-SIDED DEAFNESS.

By OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

THE first consideration in the detection of one-sided deafness is to determine the exact amount of hearing of the better ear when tightly closed with the finger or a piece of charpie. This hearing distance should be determined for both sides of the head. The principal difficulty in the problem will be in determining whether a given sound is heard by the ear under examination, or by its fellow. If one ear is possessed of normal hearing this difficulty becomes almost insurmountable. A case observed by the writer, where there was absolute deafness in the right ear, with perfect hearing in the left, furnishes important data on which to base certain propositions; it was that of a woman, I. A——, twenty-six years of age, who, at four years of age, was knocked down by a runaway team of horses. She was rendered insensible for a time, had convulsions, and her "face was turned" (facial paralysis), which exists at the present time. In a day or two it was noticed that she was deaf on the side of the paralysis; never any tinnitus; no signs of ear disease by inspection. The left ear has perfect hearing. With this tightly stopped by the finger, she hears the snapping of the finger-nails at four feet on the left side and two feet on the right side. The voice in ordinary tones is heard at a distance of 30″ on the left side and 15″ on the right. The whisper is heard 10″ on the left and 5″ on the right side, the hearing distance being about half as far on the opposite side as on the side of perfect hearing. Any sound produced on the right side and being heard, is unaffected in its intensity by opening or closing the right ear. It follows then, that in a given case, with the better ear stopped, and its hearing on either side being known, any increase in this amount on the affected side must be placed to the credit of the latter. In a given case, where a sound is apparently heard by the defective ear, and this being stopped still hears the sound as well as before, the better ear evidently is the source of the hearing. This latter test is mentioned in C. H. Burnett's "Treatise on the Ear."

Many cases will arise where the suspected ear has some hearing, but an insufficient amount to be detected by the methods already mentioned. To obviate this difficulty, a hearing-trumpet with a flexible tube susceptible of being compressed between the fingers may be used. My experience in the following case may illustrate the point: E. B. D——, aged fifty-five, had perfect hearing until July, 1883, when he fell from a ladder a distance of thirteen feet, striking his head upon the hard ground. He remained unconscious, as a result of the fall, for four weeks; he bled from one ear, and subsequently had a serous discharge from it which became ill-smelling. This discharge continued for several weeks. Tinnitus and vertigo have been constant symptoms. A firm step on the heel jars his ear very unpleasantly; has had several falls in consequence of the vertigo. No signs of middle-ear disease. The hearing for the right or good ear is nearly 10″; voice and whisper nearly normal. He had a "gathering" in this ear when a child. A great variety of tests were instituted to find whether there was hearing for even loud noises in the left ear. With a speaking-tube twelve feet in length, and passing into the adjoining room, the door being closed upon it, a loud shout through the tube was heard by the better ear, whereas a lower tone was not heard at all. Evidence of its being the better ear which heard was adduced from the fact that compressing the flexible tube made no difference in the power of hearing. To meet this difficulty I increased the length of the tube to forty-five feet, allowing it to pass into an adjoining room, with the door gently closed upon it to shut out sounds not passing through the tube. I may here remark that the rubber tube must not be of too narrow calibre (not less than 6 mm. in diameter), as in such a length the sound may pass with insufficient resonance to adequately impress the hearing if the tube be of small calibre.

Even with this length of tubing a very loud shout could be heard by the good ear while tightly stopped. The same was true with a sound produced by the striking of a metallic tongue-spatula against a large tuning-fork (producing a loud, harsh, discordant over-tone). In this case the patient failed to hear a loud sound which was inaudible to the good ear. If the sound could have been sufficiently increased in intensity without the fellow ear perceiving it, it is possible that the patient might have heard it, as, for instance, a pistol shot at the mouth of a hearing-trumpet of such length that the excluded ear could not have heard it. It will thus be seen, that tests for absolute deafness are extremely hard to find.

The tuning-fork is sometimes very serviceable in detecting one-sided deafness. In a given case, if it be placed on the teeth or on any portion of the head, it may not be heard in the affected ear, but on closing the latter there may be a certain amount of hearing, on the well-recognized principle that closing the ear augments bone-conduction. This point is developed in the *Arch. Otol.*, vol. ix., pp. 509, 510, by Dr. Knapp. Again, the tuning-fork placed upon the mastoid of the affected ear, or on the molar teeth of the same side, or over the temporal region, may be heard, apparently, in the affected ear, but in reality by its fellow. If it *is* heard by the worse ear, closure of the meatus will augment the sound, as previously stated, but if by the better ear, closure of *this* ear will cause it to be heard stronger. I at one time had a patient who was very hard of hearing in his right ear, who insisted that he heard the ticking of a watch pressed upon the auricle. On closing the fellow ear the watch was heard more distinctly, which made me suspect that the left ear heard it by bone-conduction. This, however, is an observation the exactness of which I somewhat doubt. Sometimes, by placing the base of a powerful tuning-fork against the mouth of a hearing-trumpet, especially if it be a metallic instrument, something may be gained by combining aërial with bone conduction. Another test, spoken of by Knapp in the *Arch. Otol.*, vol. ix., pp. 509, 510, is this: Pass a vibrating tuning-fork to and fro before the meatus, and in the regions of the "deaf points" there will be an interruption to the hear-

ing, which, when moved quickly, will cause a noticeable break in the continuity of the audible vibrations, provided the hearing in the affected ear is moderately good. If this is decidedly lowered the phenomenon will not be observed, but at the same time the fellow-ear is likely to hear the tuning-fork, and, for obvious reasons, without this peculiar interruption.

By this test it is not possible to differentiate between entire absence of hearing and a considerable degree of deafness. If the hearing is only moderately lowered this interference phenomenon is not likely to be observed, especially if the patient has not a well-trained ear; indeed, some of the less intelligent patients fail to recognize this phenomenon altogether, even in a normal ear.

On the whole I do not regard this test as of great practical value, but it is interesting from a scientific point of view. Another test by Knapp, mentioned in the article before referred to, is that with the pneumatic speculum. By exhausting the air in the meatus the membrane makes a certain excursion, accompanied by a click-like or rustling sound which the patient hears. The objection to this test is that it is, as far as I can observe, of little practical value. The sound made by the movement of the membrane is at best not a loud one, and of necessity it is accompanied by a *sensation* of movement of the membrane, not always so distinct from the sound produced as to enable the patient to state whether the phenomenon of rarefaction of air in the meatus is accompanied by general sensation or the production of that of sound. I have never been able to make a satisfactory diagnosis of one-sided deafness by this method. Many other tests for one-sided deafness have been used, but it is believed that those already mentioned will enable one to determine the state of hearing as perfectly as any known methods. The subject of simulated deafness by malingerers may be easily mastered by the application of the principles already laid down, provided a little ingenuity be practised.

A CASE OF GONORRHŒAL OPHTHALMIA, WITH RUPTURE OF THE CORNEA AND LOSS OF THE LENS.

By WALTER L. CARR, M.D.,

LATE HOUSE PHYSICIAN CHARITY AND MATERNITY HOSPITALS.

HUGH GILMORE, thirty-eight years of age, a native of Ireland, unmarried, and a baker by trade, was admitted August 28, 1882, to Charity Hospital, Ophthalmic Division, Dr. E. T. Ely, Visiting Surgeon. The record from the ward history book is as follows:

Previous history.—Alcoholic. "Cold in eyes" two years ago. Contracted a gonorrhœa five weeks before admission.

History of present condition.—Patient thinks that he "took a cold" in his left eye a few (4?) weeks ago. The lid became very much swollen and the eyeball reddened. Then he had very great ciliary and supraorbital neuralgia, with a profuse discharge of pus from the eye. He used domestic remedies of various kinds, poultices, tea leaves, etc. Photophobia, lachrymation and discharge became so severe that he had to stop work.

Examination.—Left eye: lids very much swollen and inflamed; great deal of dirty pus constantly flowing from the eye. Chemosis to such a degree that it is impossible to see but a small portion of the cornea, which is quite clear. There is a bulging forward of the iris; right eye congested; patient still has some gonorrhœa and has been drinking.

Treatment.—Ordered iced cloths and solution of boracic acid. Patient put in bed. Two hours afterward I went to the ward and learned that the man had gotten out of bed during the absence of the orderly, and that there had been a rupture of the cornea at its lower circumference, with loss of the crystalline lens; some of the aqueous and vitreous humors escaping at the same time. Lens was found on the floor. Patient put back in bed. Solution of atropia (gr. iv.–℥ j.) used and compress bandage applied. Supraorbital and ciliary neuralgia so great that patient can scarcely bear the bandage. . . .

September 13th. — Left eye: vision, perception of light; cannot count fingers. Tension minus.

36 WEST THIRTY-SECOND STREET.

SUBMUCOUS LARYNGEAL HEMORRHAGE.

By ETHELBERT CARROLL MORGAN, A.B., M.D.,

FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION,

WASHINGTON, D. C.

A HEALTHY, robust singer, thirty-six years of age, came hurriedly from the "Opera House" to my office, in January, 1884, stating that during the performance of a part of his rôle requiring great vocal strain and bodily exertion, his voice, which was in excellent condition, became suddenly extinct. On reaching the dressing-room at the theatre he was seized with a spasmodic cough, followed by the expectoration of a quantity of blood. The hemorrhage though not copious was continuous, having commenced about an hour before my assistance was sought. He was able to relate the above history in a voice disturbed at intervals by slight cough, a clearing of the throat, and the spitting of blood.

From the above incidents I was led to suspicion the rupture of a laryngeal blood-vessel, which subsequent laryngoscopic examination confirmed.

The laryngoscope showed that the entire left ventricular and vocal bands were bathed in blood; but after spraying the larynx with a solution of alum. grs. x. to f. ℥ j. of water, I detected that the hemorrhage proceeded from a point on the left ventricular band near its central portion. The streaks of blood could be wiped from the mucous membrane, which appeared normal, by employing a laryngeal sound armed with absorbent cotton. An insufflation of equal parts of gallic and tannic acids was made to the larynx, and a powder containing gr. ss. of opium and gr. iv. of lead acetate was administered, per orem, every three hours until the hemorrhage was checked.

Rest of voice, cold diet, and the free use of cracked ice were ordered. I visited my patient the next morning in his room; he spoke with difficulty, the bleeding had ceased, and a firm coagulum occupied the seat of previous hemorrhage. There was partial immobility of the larynx on the left, a want of approximation of the vocal bands, odynphagia, and some dyspnœa. The coagulum remained *in situ* until the third day, when complete disintegration occurred and a laryngoscopic examination revealed the fact that an extravasation of blood into the submucous tissues of the ventricular band had taken place.

After carefully cleansing the parts by means of a compressed air-spray of Dobell's solution the hemorrhage did not recur, but a large portion of the ventricular band was visibly ecchymotic and swollen. The color of the tissues underlying the mucous membrane and corresponding to the hemorrhage infiltration was reddish brown, while the left vocal band was of natural color.

This condition of ecchymosis (if it may be so called) continued for several weeks, and had not entirely disappeared when I last examined my patient, fourteen days after the accident. At this date, however, he had regained his natural-speaking voice, and the mobility of the vocal bands was apparently normal. I have since heard that it was fully three months before he could again fill his place on the programme.

I was able to discover no tubercular history in the patient, and at the time of this, his first hemorrhage, there were no signs of pulmonary disease. The solution of continuity and resultant hemorrhage were, in my opinion, attributable to the increased tension to which the laryngeal muscles were subjected.

The literature of laryngeal hemorrhage has been well

presented in recent papers; Dr. J. H. Hartman, of Baltimore, Md., having contributed a concise and practical article containing references to the more important examples.

The peculiar features of this case were the extensive extravasation of blood, the sudden aphonia, and the time required for absorption of the extravasation and restoration of the singing voice.

Cases in some respects similar to my own have been recorded by Sommerbrodt,[1] Schnitzler,[2] Fraenkel,[3] Hartman,[4] and others.

Clinical Department.

OXIDE OF ZINC IN THE TREATMENT OF WOUNDS.

Dr. Emil Steiger, of Prairie du Chien, Wis., writes: "As in none of our medical journals at my disposition, principal among them The Medical Record, have I seen mentioned the method of dressing wounds with oxide of zinc, I send to you this communication:

"About eight months ago I received, through the kindness of Professor Dr. A. Socin, surgeon in charge of the surgical department of the hospital in Basel, the annual report of said institution for 1883, and I can best benefit your readers by translating those parts of Professor Socin's preface, which refer to the use of oxide of zinc in surgery.

"After speaking of Listerism and its modifications, the powder dressings, and especially iodoform, with its great advantages and concomitant dangers, Dr. Socin continues:

"'Frequently I talked over the subject of antiseptics with my friend, Dr. Piccard, professor of chemistry, who drew my attention to the oxide of zinc. After several theoretical experiments, and after a short time of practical application, this drug proved itself in no way inferior to iodoform and bismuth as an antiseptic. At the same time oxide of zinc possesses merits, which should be fully appreciated, in the fact that it is absolutely harmless, positively odorless, and very cheap.

"'Already at the convention of the Aerztlicher Centralverein in Basel (May, 1883), I was enabled to report some surprisingly beautiful results, which we had obtained from the use of oxide of zinc. Soon thereafter I read (*Deutsche medizinische Wochenschrift*, No. 25, June, 1883) that Professor Petersen, of Kiel, had very successfully used the same remedy. But as the manner in which we make use of the oxide of zinc differs in various points from that of Professor Petersen, it will not come amiss for me to describe our method. The prominent and guiding idea is that no other antiseptic shall come in direct contact with the wound. Carbolic acid solutions, therefore, serve only for disinfection of the operating-room, the washing of hands and instruments, and the general field of operation. Sponges, after being used, are thoroughly cleansed in water, then for four weeks (the time of their being used again) soaked in a five per cent. solution of carbolic acid, and directly before using them again, well rinsed in clear water and immersed in "this zincmilk," of which more anon.

"'We use the oxide of zinc in four different forms:

"'1. A mixture of one part of ZnO. to one hundred parts of distilled water (thin zincmilk) we use for irrigating all fresh wounds, for moistening the sponges which come into contact with the wound surface, and for syringing out opened cavities of the tissues and joints, etc.

"'2. With a mixture of ten parts of zinc to one hundred parts of aq. dest. (thick zincmilk) we irrigate all wounds intended to be kept open, before their being dressed, long enough to secure a white covering or lining of the whole surface.

"'3. As dry powder the oxide of zinc is applied with a powder box to ulcers, burns, abrasions of the skin, etc., and possesses in such cases great merits.

"'4. To cover sutured wounds we use the so-called zinc-paste, consisting of fifty parts of zinc-oxide, fifty parts of water, and five-sixths part of chloride of zinc. This paste exposed to the air dries quickly up to form a hard crust, as both substances are chemically united into an oxychlorure of zinc, such as often used in dentistry. Supported by a thin layer of cotton this paste forms a hermetically closing and sufficiently adhesive cover of the wound. . . .

"'The cicatrices formed under this zinc cover are generally more beautiful and finer than those obtained from any other kind of wound-dressing. . . .

"'Quite troublesome is the so-to-say permanently necessary shaking of the zinc mixture as used for irrigating wounds, wherefore for such purpose we have lately substituted the solutions of corrosive sublimate, although these, when abundantly applied, cause sometimes stomatitis. For the treatment of wounds already septic the oxide of zinc is no more sufficient than any other antiseptics which are insoluble in water.'

"My absolute confidence in the scientific reliability of Professor Socin's statements and teachings, and the grateful remembrance of the professional advantages gained through the doctor's kind instructions in the 'auld lang syne,' induced me to use oxide of zinc in all suitable cases that came in my hands since I have read the report.

"The results justified all my expectations. When, a few days ago, one of the most prominent surgeons of the Northwest, to whom I mentioned the subject, declared that it was new to him and that he also had not seen it mentioned in any of our journals, I concluded to send you this communication."

CARBONATE OF AMMONIA IN SCARLET FEVER.

Dr. A. W. Jackson, of Brooklyn, writes calling attention to the treatment of scarlatina first brought prominently into notice by Dr. Peart, of England. This consists in the administration of from three to seven grains of carbonate of ammonia every hour for the first day, and then at longer intervals. Purgatives are to be avoided during the early stages of the disease. The writer states that he has had occasion to test this mode of treatment, and can endorse it heartily. In addition he employs the fluid extract of eucalyptus internally and as a gargle. When there is much exudation a mixture of carbolic acid and iodine in glycerine is painted over the parts. In too rapid recession of the rash, Dr. Jackson applies cloths dipped in thick mustard water, or wraps the child in blankets wrung out in hot water.

URETHRAL SPASM IN THE FEMALE RELIEVED BY COCAINE.

Dr. George Newell Hall writes that he was called to see a married lady, twenty-five years of age, who was suffering from retention of urine and considerable pain. She stated that she had been subject to these attacks from childhood, and had taken opium for their relief from the time she was thirteen years old. The spasms lasted, as a rule, for forty-eight hours, and were accompanied with considerable pain and a constant desire to urinate. An attempt to pass a catheter was unsuccessful. A grain and a half of cocaine was then dissolved in an ounce of water, and the catheter being introduced as far as the obstruction, about half of the solution was injected into the urethra. In about five minutes the catheter was again introduced and passed with ease into the bladder.

COCAINE IN STRONG SOLUTION.

Dr. C. H. Reed, of Bradford, Pa., writes in advocacy of stronger solutions of cocaine than those ordinarily employed. He uses generally a six per cent. solution, never injecting it into the tissues of the eye, and has never seen any unpleasant systemic effects. He finds that it does not materially lessen the pain of an iridectomy, and lessens but does not abolish the pain in operations upon the lachrymal sac. After the instillation of four drops of a six per cent. solution, applications of sulphate of copper or nitrate of silver are made without sensation. In operating for squint he makes four instillations of one drop each, at intervals of two minutes, and after cutting the conjunctiva drops one minim more upon the exposed tendon. In remarking upon the case reported by Dr. Peck in The Medical Record of January 17th, he states his belief that the patient was hysterical, and that the convulsions were of this nature and not due to the toxic effects of the drug.

LARYNGO-THYOTOMY FOR THE REMOVAL OF A BONE IMPACTED IN THE LARYNX.

Dr. Egbert A. Hall, of Red Cloud, Neb., reports a case of successful laryngotomy and secondary thyotomy in a child two years of age.

On September 18, 1884, the patient, while eating, suddenly began to choke and showed signs of laryngeal obstruction. These progressively increased, the patient suffering almost continuously from difficult inspiration and very frequently from attacks of coughing and strangulation. On November 12th, she was brought to Dr. Hall. No laryngoscopic examination could be made, but the diagnosis of an obstructing body in the larynx was easily made. Next day laryngotomy was performed through the crico-thyroid membrane and upper ring of the trachea. There was considerable hemorrhage, and the foreign body could not be found. A week later another unsuccessful examination was made.

"A severe inflammatory action," writes Dr. Hall, "followed, with œdema of the tissues of the neck and enlargement of the cervical glands, the edges of the wound were greatly swollen, and covered with a dirty, grayish deposit. The odor was decidedly unpleasant. The temperature rose to 103½° and remained high that week. The situation of affairs at this time was decidedly unpleasant. However, at the end of about one week the fever and swelling began to subside, and by December 12th, three weeks after our last attempt, the little patient had so far recovered as to warrant another effort to remove the foreign body.[1] I then decided to make thyrotomy, this being, as I believed, the only means of saving our patient, or removing the foreign body.

That morning the child was again placed on the table and under the influence of chloroform. Thyrotomy was made by cutting directly in the median line from the crico thyroid membrane up through the cartilage, from within out, keeping in the median line as near as possible. The incision was continued nearly to the thyroid bone. The tissues then were considerably swollen, and it was with some difficulty that we could locate the cartilages through them. Upon separating the cartilages, the obstruction was seen dislodged from its long resting-place (twelve weeks), and was floated to the surface by the free hemorrhage that followed.

The obstruction was a flat, triangular piece of chicken bone covered with a granular deposit, and with sharp points measuring five-eighths by three-eighths of an inch. Two of the angles acted as the pivotal points, causing the bone to act like a valve at each inspiration. The wound was left to close of itself without any special treatment. The child rallied nicely, without any unpleasant results from the operation. It is now only thirty-one days since the bone was removed. The wound has completely closed, and the child is rapidly recovering the use of his voice. Although he is not able to speak in a loud tone, yet he can be distinctly heard from one room into another.

During the time this case was under my care, I derived considerable satisfaction from a somewhat similar case, reported in the *Archives of Laryngology*, vol. iv., No. 1, January, 1883, reported by Ramon de la Sota, M.D., of Seville, Spain. But his case was a boy twelve years of age, mine two years and a few days. He made tracheotomy only, while I was compelled to make thyrotomy."

[1] I afterward learned that one of the physicians who assisted me November 20th, visited a patient suffering from diphtheria on the morning of the operation, and came direct from his patient's bedside to assist me; whether my patient contracted a diphtheria from him at this time, or not, I am undecided, but would not wish to submit another patient to such risks.

A SIMPLE EXPEDIENT IN THE MANAGEMENT OF STRANGULATED HERNIA.

Dr. S. H. Hurd, of Long Branch, N. J., writes: "Under the above caption Dr. C. A. Stewart, of Chicago, calls attention in The Record to a simple expedient he has resorted to successfully in five cases of strangulated hernia after taxis had failed. It consisted in dilatation of the constriction which produces the strangulation at the abdominal ring, by passing the finger along the inguinal canal, carrying the integument before it, until the constricting ring is felt. The finger is then gently insinuated into the opening, and, if the band of opposing fibres does not yield readily, gentle pressure is made against the upper border of the ring until it is felt to give way, when a resort to taxis again will ordinarily result successfully. Last year I called the attention of the members of our County Society to this plan and its happy results in several cases.

"One of my patients referred to was sixty-eight years of age, and several unsuccessful attempts had been made to reduce the hernia. I had made every preparation for surgical interference, and the patient was anæsthetized, when Dr. Green, of this city, attempted it by the above method and succeeded. The effort, though, was prolonged, and much patient and persistent pressure was made upon the fibres of the constricted ring before they yielded. This they ultimately did, but not by the 'gentle pressure' Dr. Stewart speaks of. An attack of peritonitis followed the reduction, but the patient made a speedy and happy recovery. Two similar cases treated by the same simple method, with no untoward symptoms following, warrant me in underscoring this 'simple expedient.' The first case occurred five years ago, and I do not report it with a view of establishing any priority of claim, but rather as a confirmation of the practice or plan recommended."

REDUCTION OF POSTERIOR LUXATION OF THE FOREARM OF FOUR WEEKS' STANDING.

Dr. William B. Bradner, of Warwick, N. Y., relates the case of a boy, fourteen years of age, who was thrown violently upon the ground by a playmate. Upon rising, he found that his left elbow was distorted, painful, and disabled. A physician was summoned and treated the child for twenty-nine days without relief. The patient then came under Dr. Bradner's care. Examination at this time showed slight flexion of the elbow and semi-pronation of the forearm. The olecranon was prominent posteriorly, while both condyles of the humerus presented boldly in front. The measurement of the forearm in front to the elbow, showed a shortening of an inch and a half as compared with its fellow, while to the extremity of the olecranon the measurements of the two forearms were alike. It was possible to flex the elbow by employing force, but when released it returned at once to its abnormal position. The lad was anæsthetized and attempts were made by Dr. Bradner, assisted by Drs.

Cooper and Holby, to reduce the dislocation by forcible flexion, and then by forcible extension, but without success. It was then determined to attempt the reduction of one bone at a time, and the radius was first selected. The elbow was placed over the knee of the operator at the same time that the joint was bent laterally, so as to widen the distance between the external condyle and the head of the radius. Then by vigorously crowding the latter forward, extending the forearm and rotating it inward, the radius came slowly into place. The lateral pressure was then reversed, and using the head of the radius as a fulcrum, the olecranon was pressed downward and forward, the forearm being rotated outward, and finally the ulna also came into place. The after-treatment consisted in cold affusions for a few days and then passive motion for a month, and the result was a good joint.

Progress of Medical Science.

Irritable Spine and Spinal Myalgia.—Dr. Gee defines "irritable spine" as meaning "painful spine," just as "irritable uterus" means "painful uterus." Pain constitutes the whole of the disease. Neither during life nor after death are any gross morbid changes to be detected. He takes exception to the view ordinarily put forward, that to an irritable spine may be traced a host of other aches and troubles, such as lumps in the throat, palpitation, dyspnœa, spasmodic cough, gastralgia, nausea, vomiting, irritability of the bladder, or suppression of urine. He believes all this to be a mistake, as he believes it also to be a mistake that the pain of an "irritable spine" is due to a "subacute inflammatory state of the posterior roots of the spinal nerves, or even of the spinal marrow itself." The symptoms mentioned may concur with an attack of irritable spine, but he maintains they are not the effect of it. Indeed, the idea of cause and effect must be reversed in the case of some of these supposed symptoms, such as menorrhagia. He points out the necessity for forming a correct diagnosis between two very different forms of irritable or painful spine; first, that in connection with co-existent painful affection of the spinal nerves emerging from the sensitive spot in the spine, and that in which the pain is confined to the spine, and which is usually due to myalgia; this Dr. Gee believes to be closely allied to fatigue, which may depend upon actual overwork in a fairly healthy body, or overstrain upon a muscle which is unfitted for a normal amount of work, in the case of general depression of bodily health in the sufferer. Spinal myalgia is increased by movement and diminished by rest. He illustrates this form of irritable spine, *i.e.*, that due to myalgia, by the notes of a very interesting case, in which all the features of such an affection were well marked. In conclusion, he touches upon the treatment, especially upon the necessity for careful dieting and frequent feeding. While commending rest to the muscles, he utters a warning note against the danger of condemning a patient to enforced rest in bed, or on the sofa, as likely to make the patient a confirmed hypochondriac and invalid. This portion of the treatment must be approached very tentatively, the inclination to give way to slothful indulgence upon the sofa being carefully watched and counteracted. Local applications, such as hot douches, belladonna liniment, etc., are useful in fighting this complaint.—*Medical Press.*

Inoculation of Intermittent Fever.—Professor Gerhardt recently abstracted some blood from a patient while the latter was suffering from a seizure of intermittent fever, and inoculated with this blood two healthy persons. He observed and insists upon the following precautions: 1. The locality in which the inoculation is to be made must be totally free from malaria. 2. The persons whose blood was employed for this purpose must not suffer from syphilis or any other inoculable disease. 3. The persons to be inoculated must agree to the experiment and voluntarily subject themselves to it. 4. The temperature record of the individuals to be experimented upon must have been carefully kept for some time preceding the experiment, and evince not the least increase of temperature. They must have been at the time of the operation, and for a long time preceding the same, utterly free from all febrile symptoms. The experiments themselves gave the following result: 1. The intermittent fever caused in this manner, by inoculation, is distinguished from the natural malarial fever by greater irregularity of the attacks of the former. 2. After a number of single or group-wise attacks, a regular quotidian, analogous to the form present in the original source, developed itself in the one person on the twelfth day, in the other on the twenty-fifth. 3. The fever thus artificially produced reached in both cases such a high degree (temperature as high as 106° F., and duration of fever fully twenty-four hours), that the experiment had to be interrupted by the administration of quinine. 4. There is no doubt that the pathogenic element of malaria is present in the blood of a patient suffering from intermittent fever at the time of a seizure, and that it is then, together with the blood, inoculable. 5. With very few exceptions, all the seizures by which the inoculated persons were attacked set in at the hour at which the inoculation had been made, or if they had not done so (as was the case a few times), they reached their acme at that time. The period of incubation was difficult to determine; the first febrile movement made its appearance in the one case on the seventh, in the other on the twelfth day, and the graver series of seizures began in the one on the seventeenth, in the other on the twenty-fifth day.—*Zeitschrift für Klinische Medizin.*

The Treatment of Phthisis.—Dr. J. Burney Yeo, in the London *Medical Times*, December 6, 1884, gives his ideas on the treatment of phthisis as follows: 1. In the first place, to prevent or amend those faults of constitution, organization, and development which predispose to the acquirement of this disease. 2. To prevent or cure those local pulmonary affections which may induce a tendency to this disease, even where no constitutional predisposition is found to exist. 3. To prevent the possible spread of the disease by the conveyance of its germs from the sick to those who are necessarily brought into close contact with them. 4. To endeavor, so far as possible, to antagonize the influence of the infective organism *in situ*, and in its action on the constitution. To attempt to hinder the progress of its development and reproduction, and its extension to the sound parts of the affected lung, and also to the sound unaffected lung, and to prevent the infection of other organs. This is what is understood by antiseptic treatment. 5. To lessen and remove the *fever* and other constitutional disturbances dependent on the infection of the constitution, as well as on the local inflammation. 6. To lessen and arrest the local irritation and inflammatory and catarrhal changes when evidences of such make their appearance. 7. To improve the disturbed and defective nutrition by all the means in their power, medicinal, regimenal, climatic, etc. 8. To relieve the various distressing symptoms that occur during the course of the malady. 9. To diminish as far as possible the evil consequences of the several grave complications incident to its course.

Phlegmasia Dolens.—It appears that notwithstanding the numerous works and discussions on phlegmasia alba dolens the subject has not yet been exhausted. Dr. Brun, of Paris, has just written a work on the subject which throws some new light on its symptomatology. He considers the disease under two forms. The first occurring as a malignant affection from its onset, and causing speedy death; the second appearing as incidental in the course of a general pathological condition. The first, or infectious form, has been well known since the time of Velpeau. The second form the author subdivides into latent, com-

mon, and lymphangitic. The latent form comprises those cases of sudden death from dyspnœa in severe diseases and after childbirth, in which the autopsy shows venous thrombosis of the limb, from which detached particles have been carried into the circulation and obstructed the pulmonary artery. The common form is passed over, as it has been so often described. The lymphangitic form is described as presenting a bright rosy color, diffused pains, which disappear slowly, great increase in the temperature of the limb and long-persisting œdema. The complications are: periphlebitis, consecutive arteritis, gangrene, and especially pulmonary emboli. The author regards a pre-existing lesion of the vein as the pathogenic cause. It may be due to vitiated nutrition, cachexia, or some severe febrile condition. A part of his observations, however, show that the nervous system deserves a share of attention. The views advanced by other recent writers on this disease are also of interest. Dr. Esler reports in the *British Medical Journal*, September, 1884, two cases of phlegmasia dolens occurring on the right side in patients who had, during and after labor, lain continuously upon the right side. Dr. Dill, of Belfast, believes that one position long maintained may have something to do with the affection, but holds that the wearing down of the system from hemorrhage and irritation of the womb often induces it. Dr. Macartney relates in the *Indian Medical Gazette*, of November, 1884, the case of a young soldier, who, after suffering pain in the left iliac fossa with obstinate constipation for ten days, during which time his temperature rose regularly each evening, suddenly experienced a severe pain in the left groin and the limb began to swell, reaching nearly twice the size of the normal leg. The pain was excruciating and not relieved by hypodermics of morphia. The swelling was uniform, elastic, but not pitting on pressure, there was œdema about the ankle. After four days improvement began, but was very slow, the limb being powerless, and attempts to move it causing dull aching pain. The author regards the case as one of phlegmasia dolens differing in no essential point from the disease as it occurs in lying-in women. The obstinate constipation, with pain in the left iliac fossa appears to have been the exciting cause, just as pressure of the fœtal head in this region, followed by pain and malaise, is believed to produce the disease in the puerperal woman. Another case is mentioned as having occurred in the same hospital, a short time before, in a man recovering from enteric fever.

Cocaine in Alcoholism.—Dr. Fleischl, of Vienna, is recently reported to have found in cocaine a rapid and satisfactory cure for alcoholism, morphinism, and allied habits. The nervous symptoms which arise upon either withdrawing the drug abruptly or by degrees are treated by the hypodermic administration of the muriate of cocaine. It is claimed that in ten days a cure may be effected. The dose is from a quarter to half a grain dissolved in water.

Causes of Death in New-born Children.—Dr. Nobiling, of Munich, whose labors in forensic medical research have earned him the reputation of a high authority in Bavaria, has recently published a series of contributions on the pathological appearances observed in the bodies of children that have died from asphyxia shortly after birth. He has examined a large series of bodies, and has arrived at the conclusion that the asphyxia often attributed to overlaying, and even to obscure pulmonary disease, is too often due to foul play. He is particularly suspicious of extravasations of blood, and presents some conclusions on that subject. Extensive subcutaneous extravasations could always be traced by Dr. Nobiling to external violence, including such as might be received in protracted and instrumental labor, and attempts to restore animation. Effusions of blood in the muscles of the neck and along the course of the great vessels are always caused by forcible strangulation. Hemorrhages under the capsule of the liver or in its substance are invariably the result of external pressure, and so are lacerations of the peritoneum, liver, spleen, and kidneys. These injuries are by no means rare results of violent attempts to promote respiration, and Dr. Nobiling has traced them also to rough and clumsy handling of a new-born infant by male relatives or incompetent nurses. Hemorrhage in the tissues of the umbilical cord are very rarely caused by the mechanical forces of labor, or even by artificial replacement of the prolapsed cord; they generally result from firm manual pressure on the cord, or from intentional laceration. Circumscribed collections of blood under the scalp or integuments may be either due to mechanical labor, or to many other kinds of external violence; the same applies to hemorrhages in the substance of the lips, tongue, palate, and pharynx, which are always traumatic. Bleeding from the external auditory meatus and extravasations behind the ear are also the results of violence, not disease. Dr. Nobiling has often found a portion of the fluid or solid material which caused the infant's death in the nasal fossæ, mouth, larynx, trachea, bronchi, pulmonary vesicles, œsophagus, stomach, tympanum, or Eustachian tube, sometimes in only one of these anatomical structures and regions. When blood is found lying free in the same parts, it may have proceeded from the infant's nose, or have entered its mouth during parturition, being of maternal origin. The principal lesson to be learnt from the researches of Dr. Nobiling is that all internal and intestinal extravasations of blood in the body of an infant are to be regarded with suspicion, and to be considered as traumatic, being due to violence causing visceral injury, or complete and sudden asphyxia.—*The British Medical Journal*, December 6, 1884.

Peptonization.—An observation communicated by M. Marcano to the Academy of Sciences is suggestive of what may prove a valuable process for the conversion of albuminoids into peptones. If a small quantity of the fresh sap of certain plants—the agave, for example—be added to chopped meat first covered with water, and the mixture be kept at a temperature of 102.2°–104° F., an active fermentation is immediately set up, with evolution of inodorous gases. At the end of thirty-six hours the fibrin has disappeared and a liquid is left containing peptone equal in weight, when dried in a stove, to one-fifth of the fresh meat used. This fermentation appears to M. Marcano to be due to the vital action of micro-organisms, and to resemble the peptonization of the gluten of flour by a bacterium which is said to take place in bread-making. In confirmation of this view it is stated that if the juice of the plant be saturated with chloroform the fermentation is not set up. Moreover, a "mucorinée" may be cultivated by sowing a few drops of agave sap in sugared water. This mucorinée is capable of completely dissolving fibrin in the presence of water. A large number of other fruits and juices are stated to be endowed with properties similar to those possessed by the sap of the agave. Papaw juice is said to be relatively weak compared with the peptonizing activity of other juices which contain no digestive principle like "pepsin." M. Marcano is of opinion that the new method of peptonization will afford a simple and economic means of preparing pure peptone quickly and at a low price, and suggests that it might be applied upon a large scale, so as to allow of the export of meat from South America in a form more nutritious and economical than the extracts.—*London Lancet.*

Laparotomy for Perforation of the Stomach and Intestine.—According to Mikulicz, laparotomy is indicated in all cases of perforation of the stomach or intestine due either to direct or indirect violence, or to some pathological process. Existing peritonitis should not contra-indicate the operation, as it may be thus effectually treated. The main contra-indication of laparotomy in such cases is extreme exhaustion. In the first of his reported cases, the author of this paper had to

deal with perityphlitis, which after a time became complicated by constipation, vomiting, and other symptoms of intestinal obstruction. Laparotomy was performed, and an incision, six inches in length, made in the linea alba. The abdominal cavity contained about two pints of very fetid fluid. The intestine, though bound down by numerous adhesions, showed no signs of any disturbance in the circulation. The patient died five days after the operation, and on post-mortem examination the seat of perforation in the intestine was first discovered. The second case was one of a young man who, after having suffered from diarrhœa during six weeks, became constipated during the seventh week, and presented symptoms of ileus. The case was diagnosed as one of volvulus. On the performance of laparotomy, one pint of turbid serous fluid was found in the abdominal cavity. A volvulus was found, and the obstruction removed. The patient recovered from the more direct effects of the operation, but after an interval of a few weeks succumbed to intercurrent pneumonia. The patient in the third case was a young man who, having been disturbed during sleep, and having suddenly sprung out of bed, was seized with intense pains in the umbilical region, and presented symptoms of obstruction. Sixty hours after the onset of these symptoms the patient came under the care of Professor Mikulicz, who diagnosed intestinal incarceration, and at once performed laparotomy. In the abdominal cavity he found about a pint of thin badly smelling pus, and some undigested pieces of potato. On the left side, just above the brim of the pelvis, a perforation, six millimetres in length and four millimetres in breadth, was observed in a knuckle of the ileum. The mesenteric glands were much swollen, and as no other cause of the lesion could be determined, Professor Mikulicz came to the conclusion that this case was one of perforating ulcer from typhoid fever. The edges were refreshed, and brought together in the long axis of the opening by a dozen sutures of silk. The subsequent course of the case was satisfactory, although the abdominal wound opened up and gave exit to a considerable quantity of pus. In the fourth case, laparotomy was performed for rupture of the stomach. The opening existed near the diaphragm, in the smaller curvature. The patient, whose stomach had been much distended, and whose abdominal cavity was filled with portions of food, died three hours after the operation.—*Centralbl. für Chirurgie*, No. 45, 1884.

The After-treatment of Vaccine Vesicles.—Dr. F. P. Atkinson suggests the following directions to be given after vaccination. 1. If the arm become red and inflamed, apply powdered oxide of zinc, starch, or flour. 2. Never apply moisture of any kind, whether in the shape of a poultice or cold compress, as it tends to convert the vesicles into open sores. 3. Never apply oil to prevent the clothes from sticking to the arm, as it will do nothing of the kind. If the scabs be rubbed off and the marks be deep and not inclined to heal, it is best to apply some small pieces of lint (of just the size of the sore) soaked in dilute nitric acid lotion (seven minims to the ounce), and keep them covered with oiled silk.—*British Medical Journal.*

Some of the Early Signs of Ataxy.—Dr. Jacquemart, in the *Journal de Médecine de Bruxelles*, describes certain urinary symptoms which may occur in a very early stage of locomotor ataxy. It has already been pointed out by Fournier, and also by Guyon, that locomotor ataxy may commence insidiously with certain vesical disturbances; and that the subjects of this disease are often at its commencement affected with symptoms that might impose on the medical attendant, and lead him to suspect some decided and severe lesion of the urinary passages—as, for instance, cystitis, calculus, or stricture. The symptoms of morbid condition of the urinary organs vary much in form. The most frequent symptom, according to Fournier, is sluggishness of the bladder without retention. The urine cannot be passed save with considerable effort, and the patient has often to wait long for the appearance of the stream. This symptom is observed most frequently in the early morning. In some cases the patient complains of the micturition being prolonged and frequently excited, and sometimes of the stream being suddenly arrested. Incontinence is also a frequent symptom. This differs in character from the incontinence due to organic disease of the bladder, as it is essentially intermittent, takes place usually at night, and is always partial and incomplete. A third class of disturbances consist in frequent desire to micturate, and painful spasm of the bladder or vesical colic. Another morbid condition, though much less frequent than the others, is vesical anæsthesia. It is held by Dr. Jacquemart that, when the medical attendant observes such vesical disturbances, the etiology of which cannot be made out, he ought to suspect tabes, even in the absence of any marked symptom of this nervous affection. Again, where the vesical disturbances coexist with any of the ordinary symptoms of ataxy (abolition of patellar reflex, visceral crises, ocular disturbances), tabes should be diagnosed, even in the absence of any decided disorder in the coördination of movements. Dr. A. Pitres (*Le Progrès Méd.*, No. 28, 1884) relates three cases in which weariness and sudden fatigue, and pain in the muscles of the limbs and loins, preceded the development of the characteristic symptoms of locomotor ataxy. He thinks these symptoms differ from those of ordinary physiological fatigue by their abrupt onset, the absence of any previous exertion, and their rapid disappearance after a relatively short time, and the complete integrity of the muscular sensibility during the intervals. He regards them as the clinical equivalents of the other crises affecting the stomach, intestine, kidney, bladder, etc., which supervene frequently at the beginning or during the course of locomotor ataxy, and which often permit a diagnosis to be made before any incoördination of movements or lightning pains in the legs have appeared.

The Forced Feeding of Phthisical Patients.—Dr. Störk, of Vienna, describes (*Wiener Med. Blätter*, December 25, 1884) a method for the enforced feeding of phthisical patients, which he has introduced lately, in place of the meat-powder given by the stomach-pump, to which some patients greatly object. He prepares a mixture of finely triturated ham, mixed with milk, and introduces it, by means of a syringe, through a catheter, which is passed down only as far as about the level of the larynx. This is much better borne by the patients than the other method; and, when pain was present, interfering with the introduction of the catheter, he found that it was entirely prevented by brushing the fauces with a twenty per cent. solution of hydrochlorate of cocaine.

Notes on the Use of Antipyrin and Kairin.—Dr. Metropolsky (*Meditz. Obozr.*, No. 21, 1884) believes that antipyrin outrivals all other means at present known for reducing the temperature of febrile patients. He believes it is indicated in cases of enteric fever and croupous pneumonia where the temperature rises above 104° F. Being here administered, antipyrin surely, safely, and considerably lowers the temperature for ten to eighteen hours. As the drug is prone to give rise to heartburn and sickness, it is better to use it in enemata (sixty grains in three twenty grain doses, at intervals of an hour). In the same journal, Dr. B. Kostyleff, of Tver, writes that he has administered antipyrin in relapsing fever, enteric fever, and pulmonary phthisis. From his observations he draws the following conclusions: 1. Antipyrin is a powerful antipyretic, but it must be administered in large doses (thirty grains for the first dose, followed by several fifteen-grain doses at intervals of one hour, to an adult. However, it is not an absolutely reliable agent, since even drachm doses sometimes bring about but a slight antipyretic effect, or even no effect whatever. 2. Cardiac weakness

does not contra-indicate the administration of antipyrin. 3. The drug is not so well borne by the patient as some observers assert. It often produces nausea, vomiting, and abdominal pain. 4. Its antipyretic action develops itself very rapidly—the fall of temperature beginning within less than an hour after the administration of a dose. The fall is accompanied by profuse perspiration. When antipyrin is introduced through the rectum, the temperature falls more slowly than when the drug is given internally. 5. The general state of the patient improves proportionately to the degree of decrease of temperature. 6. The re-elevation of the temperature begins usually in less than twelve hours, and sometimes is accompanied by rigor. 7. Children bear antipyrin better than adults. Dr. Pushkareff, of St. Petersburg, having studied the action of kairin in eight strong patients with petechial typhus, arrived at the following conclusions: 1. Kairin markedly lowers the temperature in all cases of typhus fever. 2. In some cases the temperature may be kept at a low level by the contiued administration of kairin, but in other cases it again reaches high figures in spite of the repeated use of large doses of the drug. 3. Besides the changes in the temperature, the drug does not produce any other influence on the course of typhus fever. 4. The high price of the drug, the difficulty of dosage, and the injurious action of kairin on the red blood-corpuscles, prevent any practical use of kairin in the treatment of typhus fever. He also saw collapse from the use of the drug in a case of typhoid. In the *Gazzet. degli Ospitali*, No. 104, 1884, Dr. Mingazzini gives details of several cases where antipyrin and kairin drugs were used together. The mixed drugs produced a much more marked fall of temperature than an equal quantity of either drug given separately. The lowering of temperature also lasts longer. Kairin, administered with antipyrin, does not give rise to the inconveniences that are apt to follow it when given by itself.

Paralytic Obstruction of the Intestine.—Dr. G. Thibierge has described some cases of intestinal obstruction caused by paralysis of the muscular coats of the gut and consecutive retention of the fæces. This paralysis may occur after the reduction of a strangulated hernia, or after an attack of peritonitis, but it is more often due to some nervous lesion. It is generally observed in old people suffering from habitual constipation. Vomiting is frequent when the obstruction has lasted some time, and often recurs every time the patient takes nourishment. The abdomen is much distended, and there may be a good deal of pain. When death occurs at that period, it is caused either by inanition or by asphyxia. In some cases there is a temporary improvement, followed by fatal collapse. Generally, however, recovery takes place after the obstruction has been relieved. The best treatment consists in galvanization of the intestine. —*London Medical Record*, February 16, 1885.

Scrofulous Neck.—Dr. Clifford Allbutt thinks that the chronic enlargement of the glands of the neck, known as scrofulous neck, is secondary to irritation in the associated mucous membranes, and absorption therefrom; the chief of these being the mouth and throat, and the next in order the nasal, aural, and ocular surfaces; and sometimes from irritation upon the skin of the face and head. Speaking of the treatment of these cases, the author says that a residence at Margate, together with careful dieting and nursing, is the best means of cure in cases which are not far advanced. The cautious use of mercury, such as the solution of the bichloride with tincture of iron, is very good, unless the inborn frailty be very marked; and iodides with iron are likewise valuable. External applications should be used with caution. So soon, however, as the glands become adherent, either to each other or to the surrounding tissues, then it is most desirable to call in the surgeon, and to extirpate every caseous gland or portion of a gland. Mr. Teale has devoted much time, and has had great experience in operating on these cases, and it is due to the combined exertions of Dr. Allbutt and Mr. Teale that numerous cases have been restored from a state of misery to enjoy a life of comparatively good health. The scar remaining after the operation is small, and after a year or two not very noticeable, provided the drainage be not kept up too long; it is better to risk a second operation than to keep the drainage-tube in for too long a period.—*London Medical Record*, February 16, 1885.

Erysipelas Inoculation.—The results of an inoculation of erysipelatous virus in a case of carcinoma mammæ, in which an operation was impossible, are related by Professors Janicke and Neisser in the *Centralblatt für Chirurgie*, No. 25, 1884. A particle of erysipelatous virus about the size of a pin's head from a pure culture was rubbed into a freshly scarified spot on the surface of the morbid growth. The same evening the temperature was 104.2° F., and the next morning 104.6° F. Almost the whole of the left pectoral region was now erysipelatous, and by evening the right side was also involved. The temperature had risen to 105° F. On the three following days the morbid process spread over the entire breast and abdomen, the right arm and part of the neck. The patient died on the fourth day in collapse. A cancerous gland under the clavicle softened on the second day and had entirely disappeared on the fourth as a result of the inoculation. The whole cancerous mass was softened and diminished in size. Masses of the cocci of erysipelas infiltrated the whole tumor, causing in many places a dissolution of the cancer nests and completely filling all the lymphatic spaces. The cancer cells and nests were perishing before the advance of the erysipelas cocci.

Prepuce Grafting.—Dr. Lucas writes in *The London Lancet*, "I have found grafts from the surplus skin of the prepuce to adhere when those from other parts have failed." Skin from this source, owing to its suppleness, thinness, and vascularity, appears to be peculiarly adapted for transplantation. The writer had a case of acute cellulitis under his care some three years ago, which resulted in extensive loss of skin, both in the thigh and leg. In this case when the granulations had assumed a healthy appearance grafts from various sources were placed upon the wound. The superiority of the prepuce skin over that of the coarse skin of an amputated finger with the dry cuticle upon it was marked. It adhered more certainly and grew more rapidly. The time which may be allowed to elapse between the removal of the skin and its application in the form of small grafts to a wound is not accurately determined. Dr. Lucas has allowed at times from half an hour to an hour to elapse before using the skin removed, without attempting to maintain it at the temperature of the body. He believes that if necessary it may be carried in a bottle or wrapped in guttapercha paper for some hours without loss of vitality.

The Treatment of Asthma.—According to Dr. Rodet, the best means of overcoming a paroxysm of asthma consists in subcutaneous injections of morphia and inhalations of iodide of ethyl. Twelve drops of the latter, poured on a handkerchief and inhaled, procure almost immediate relief. The different papers and cigarettes which have been recommended are worthy of a trial, but soon lose their efficiency. Between the attacks, a change of air and of occupation is often essential. In catarrhal asthma, the treatment must be directed against the bronchitis and laryngitis, which are often benefited by a stay in a warm climate. According to M. Hardy, very good results are sometimes obtained by means of a blister applied to the thigh or arm. In nervous asthma, bromide and iodide of potassium are the most useful remedies, especially the latter. Gymnastics and baths of compressed air can also be recommended. —*Journal de Médecine de Paris*, No. 25, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 21, 1885.

RECENT PROGRESS IN MEDICAL EDUCATION.

WE have had occasion several times to refer to the question of medical education, and we are sorry to say we have not been able always to do so in very flattering terms. It is natural that the facilities for higher education, and especially for professional education, in new countries, should not be equal to those of old and long settled lands. The first work in a new country must be preparatory, and the workers have a task before them which allows them little leisure for intellectual progress. Doctors and lawyers and clergymen are needed indeed, and must be had, but neither time nor money can be spared to provide those intending to follow these pursuits with more than the minimum knowledge that will enable them to perform the duties of their respective vocations. And the character of the professional schools must conform to those requirements. But, as time goes on, the first difficulties are overcome, the country becomes settled, men have the leisure and the means to devote themselves to intellectual pursuits, and they seek for the opportunities, at home if possible, abroad if must be, to follow their desires. Thus a demand for a higher professional education is created, and the schools must satisfy this demand. We are speaking now more particularly of medical schools, what they have done and are doing. It can no longer be said that a young man who is in earnest cannot get a thorough and scientific medical education in this country. But something more than this is needed. It should be impossible for any incompetent or half-educated man to obtain a degree. Although we have not yet reached this standard, there are hopeful signs that we are approaching it. The colleges themselves, either from self-interest or for some other reason, cannot be always relied upon to take the initiative in this direction, and outside pressure is needed to force many of them upward, whether they will or no.

The Illinois State Board of Health is showing a commendable regard for the welfare of the citizens of that State, by insisting that their medical advisers shall be competent physicians. The Board adopted, in 1880, a schedule of minimum requirements, as a standard with which the medical schools were required to comply before their diplomas could be accepted. The diplomas of colleges which give evidence of an actual and *bona fide* compliance with this schedule, are accepted as sufficient warrant for the certificate of the Board required by law before any one can practise medicine in the State. The diplomas of colleges which do not give such evidence are supplemented by an examination before the Board on the subjects of the schedule omitted. From a small volume entitled "The Conspectus of the Medical Colleges of America," compiled by this body, we learn that there are now in the United States and Canada 128 institutions of medical education of all classes which are empowered to grant degrees. Of this number there are 102 which exact an educational requirement as a condition of matriculation; a gratifying increase from 45, the number at the time the first "Conspectus" was issued. Attendance on three or more courses of lectures before graduation is now required by 35 colleges as against 22 heretofore. Hygiene is now taught in 80 colleges, and medical jurisprudence in 92, as against 42 and 61 respectively heretofore. The average duration of the lecture term has increased from 23.5 weeks to 24.5 weeks, and 4 more colleges have lecture terms of five months or over, and 11 more have terms of six months or over, as compared with the preceding session. These figures are in a measure satisfactory, as showing a slight improvement, but they show also that there is still need of much greater improvement before we can regard our system of medical education with much complacency. The Illinois State Board of Health has found a way to force the colleges up to their duty, and if all the State Boards would follow their example in obtaining laws through which a definite standard could be set up, the colleges would soon find it to their interest to conform to this standard. It is gratifying to learn from this "Conspectus" that there is now but one bogus college in the country, but it is at the same time disgraceful that even one should be permitted to exist with the power to grant medical degrees.

THE TOXICITY OF URINE AND ITS CAUSE.

IN 1880 M. Pouchet discovered in normal urine a chemical body which comported itself like an alkaloid, and which, when combined with hydrochloric acid, gave double salts with platinum, gold, and mercury (Pouchet, "Thèse de Paris, 1880," *Progrès Medical*, December 20, 1884). The investigations of Selmi, Gauthier, Brouardel, Boutmy and others, by which a knowledge of the cadaveric alkaloids has been obtained, led also to the hypothesis that the urinary alkaloid was to be classed with these ptomaines. Quite recently Professor Bouchard (Soc. de Biologie, December 6, 1884) has announced the results of his investigations into the toxicity of normal urine. These throw additional light upon the cause of this toxicity, and are pregnant with suggestions for further practical and scientific investigation.

M. Bouchard believes that he has demonstrated the three following propositions:

1. There exist alkaloids in the body of healthy living individuals.

2. These alkaloids are manufactured in the digestive tube, and are apparently elaborated by the micro-organisms of intestinal putrefaction.

3. There are alkaloids in normal urine which represent a part of the intestinal alkaloids, absorbed by the intestinal mucous membrane and eliminated by the kidneys.

The method by which Bouchard reached the conclu-

sion that toxic alkaloids exist in the urine is instructive. It consisted in injecting urine and solutions of known amounts of the different constituents of the urine into the veins of living animals of known weight. First, pure water was injected, and it was found that 90 c.c. of water per kilogramme of body-weight could be injected without inconvenience, and that 120 c.c. per kilogramme had to be introduced into the circulatory system before death was produced. Smaller amounts of liquid than this were always employed in his experiments.

Normal urine was then injected into the veins of frogs and rabbits. From fifteen to twenty drops were sufficient to kill a frog. Toxic doses injected into rabbits produced symptoms of muscular weakness, contracted pupils, diminished respiration, lowered temperature, torpor, and finally death from arrest of respiration.

The toxicity of urine being established, Bouchard undertook a series of experiments in order to determine which of its constituents were the active agents. As regards urea, the results of the investigations of Grehant and Quinquand (*Journ. de l'Anatomie et de la Phys.*, September, 1884) were substantially confirmed, viz., that urea is poisonous, but only in very large doses. It is necessary, according to Bouchard, to inject 6.66 grammes (over one and a half drachm) per kilogramme of animal in order to cause death.

Uric acid, which is generally stated to be innocuous, could be injected with impunity up to a dose of 34 ctgr. per kilogramme of animal.

Creatin and creatinine were found to be inoffensive. The inorganic salts, though toxic in very large doses, produce altogether different symptoms from those of urinary poisoning.

When the urine was filtered through charcoal and deprived of its coloring matter, it lost one-half of its toxic properties. Hence this coloring matter is slightly poisonous.

The toxicity does not depend upon its volatile constituents, because the urine is still poisonous after ebullition, and in aqueous and alcoholic extracts.

If a person have a slight catarrh or indisposition, the toxic properties are at once augmented.

The poisonous alkaloids seem to reside in alcoholic as well as aqueous extracts. But the alcoholic extract does not produce contraction of the pupil and does cause salivation. On the other hand, the aqueous extract causes toxic symptoms similar to those produced by urine itself, symptoms which are not very unlike those of uræmia.

RECENT CONTRIBUTIONS TO THE STUDY OF CANCER.

Dr. C. Partsch has made a careful analysis of the records of the cases of cancer treated at the Royal Surgical Clinic at Breslau since the introduction of antisepsis in 1875. His statistics cover only cancers of the lips and external genital organs. There were 98 cases of cancer of the lips, 88 in males and 10 in females. The average age of the patients was 57.3 years. As to etiology, 73 per cent. of the men had been greatly exposed to wind and weather, while tobacco-smoking seems to have had a very slight influence. In 12.2 per cent. an injury was the exciting cause. Of those operated upon 4 died soon after the operation, 8.3 per cent. died later of intercurrent affections, and 32.2 per cent. died from a recurrence of the disease. Metastases to internal organs were not observed.

The entire limit of life from the inception of the disease in those with a relapse and a secondary operation was on the average 3.22 years, or about 17.1 months after the first operation. Partsch reports 35.4 per cent. who had had no relapse for a space of from 1 to 9 years.

Cancer of the penis was observed twenty-one times, most frequently at the age of forty to sixty years. Of the patients operated upon 17.6 per cent. remained healthy. Of the rest, in some it was from 2½ to 3 years before the tumor recurred. After a second operation, death followed in the course of 13.2 months.

Cancer of the vulva was observed nine times. Of six patients operated upon, one had remained healthy for 3 years. The rest died of relapse or intercurrent troubles. Hofmeier, of Berlin, has made an interesting contribution to our knowledge of uterine cancer (*Zeitschr. f. Geburtshilfe u. Gynakol.*, 1884, Bd. x., Hft. 2). The material upon which he based his studies consisted of 603 cases of cancer of the uterus, among 16,800 patients at the Poliklinik, and 209 cases among 9,400 patients in Schroeder's private practice, the duration of time being ten years.

To begin with, it will be seen that the proportion of cancer cases in presumably sick women is 3.6 per cent. for charity cases and the poorer classes, 2.18 per cent. for the better classes. This is in opposition to the general view that cancer attacks the poor less frequently than the rich. Of those affected, 21 per cent., or over one-fifth, were nullipara. This again is in marked contrast with the experience of Emmet and others.

The disease was situated 238 times in the portio, 181 times in the cervix, and 28 times in the body, only 3.4 per cent. being in the last situation. The average age of those suffering from cancer of the portio, cervix, and body was 42.47 and 54½ years repectively. One hundred and sixty cases were operated upon with a view to permanent cure. Nineteen per cent. of these died in consequence of the operation; of 105 operations for disease of the vagina 13 died (12.3 per cent.); of 8 Freund's operation 5 died (62 per cent.); of 34 vaginal total extirpations of the uterus 9 died (26 per cent.); of 13 laparotomy operations 4 died (30 per cent.). These statistics are in favor of vaginal total extirpation. Later experiences confirm the value of this method still more strongly. Thus Staude, of Hamburg, reports 16 vaginal extirpations of the uterus without a death in consequence of the operation. The results of these operations as to recurrence of the disease is best shown in the following table:

There remained healthy after two years: 1, after extirpation of uterus by laparotomy, 80 per cent.; 2, after Freund's operation, 32 per cent.; 3, after vaginal total extirpation, 33 per cent.; 4, after supravaginal and vaginal amputation, 32 per cent.; 5, after amputation with *ferrum candens*, 42 per cent.

A survey of the foregoing leads one to the reflection, how ineffective still is modern surgery and therapeutics! Out of the 812 cases of cancer there were 652 who were only treated with palliative remedies. Out of the remaining 160, for whom radical relief was attempted, 30 died in consequence of the operation. Of the 130

left, about two-thirds died within a year or two, leaving some forty-four lives saved, for two years at least, out of the 812. The mortality from cancer is, therefore, at the very best, about 95 per cent.

THE QUESTION OF SURGICAL OPERATION ON GENERAL GRANT.

During the past week the local disease of General Grant has shown no marked tendency toward progressive ulceration. At the recent weekly consultation, Dr. Fordyce Barker was unavoidably absent. Drs. J. H. Douglas, Henry B. Sands, and George F. Shrady, who were present, made a thorough examination of the General's throat, with a view of discussing the expediency of a radical surgical operation for the removal of the growth. Such a measure would involve the division of the lower jaw in the median line, the extirpation of the entire tongue, and the greater part of the soft palate, together with the removal of the ulcerated and infiltrated fauces, and the indurated glandular structures under the right angle of the lower jaw. This was considered mechanically possible, despite the close proximity and probable involvement of the tissues adjoining the large arteries and veins in the neighborhood of the ulcerations; but in the best interests of the distinguished patient the surgeons did not feel inclined to recommend the procedure. Even by such means there could be no guarantee, in view of extensive surrounding infiltration, that the limits of the disease could be reached without immediate risk to life by the severe shock to a constitution already much enfeebled. The low vital power is such a strong element in the decision that, for the present at least, no kind of operation will be undertaken. The ulceration on the side of the tongue has not progressed far enough to produce the usual intolerable pain associated with that condition, but should the latter symptom appear, it may be deemed advisable to divide the gustatory nerve.

The general tone of the patient's system remains about the same as at last report, notwithstanding he has suffered much from insomnia. The latter, within the last day or two, has been kept under control by a suitable anodyne. There is no pain in swallowing, and sufficient food is taken with a reasonable relish.

THE NEEDLESSNESS OF THE FEAR OF CHOLERA.

It will be found during the coming spring that the prospect even of an epidemic of cholera works considerable harm. The agitation over the subject has aroused the people, and has not only stimulated health officials but has infused among the people a very widespread fear of the expected disease. Indeed, there is in many nervous persons an almost panicky condition of mind, while even the most intelligent have an exaggerated view of the direful possibilities which the coming season holds out. The result is that nearly all the families which usually leave the city in the summer are now planning to leave it much earlier than is customary. Medical men will be among the first to feel this, in the earlier decrease of work and income which the summer season brings.

We have felt it to be the wisest plan, and, indeed, our bounden duty, to urge as strongly as possible the need of setting on foot the most thorough preventive measures against cholera. To spend money to keep out the disease is by far the cheapest and most humane plan. If, now, the disease does not come, at least duty will have been done, and the people will have received some useful lessons in sanitation.

It should be understood, however, that the probability of there being any extensive outbreaks of cholera in this country, during the coming year, is small, while the probability of any but sporadic cases appearing in this city is very remote indeed. The cholera is now in the third year of its travels from India, and its virulence is waning. This was shown by the small extent of its ravages in Paris last fall.

There is absolutely no need for alarm or of early decampments into cold and unsalubrious summer hotels. It is necessary to repeat, also, the statement that cholera is not a contagious disease like scarlet fever and measles. Its presence in cities of India, where it is endemic, creates no more alarm or comment than does the presence of diphtheria with us.

DENTAL MALPRACTICE.

Dentists are likely soon to realize the responsibilities of treating diseased teeth and leaving them in the patient's jaws. Dr. Osmun, of Newark, N. J., reports a case in the *Dental Cosmos* of a lady who had a wisdom tooth "treated" and filled, and seven months afterward it was discovered that an extensive alveolar abscess had developed at the root; this was followed by great rigidity of the jaw, necrosis, absorption of pus, and pyæmia. The woman had previously been in excellent health. Dr. Osmun said: "I had the hardest work in the world to keep that woman from bringing a suit for malpractice against the dentist who had filled the tooth." It would be well for dentists to remember that the treatment of diseased tissues requires a medical education.

SYPHILIS AND THE DEPOPULATION OF FRANCE.

The members of the Académie de Médecine have recently held several long debates upon the subject of the depopulation of France. Like most of the Académie's prolonged discussions the result has been rather empty. At the last meeting, however, something definite was brought forward by M. Fournier. The depopulation of France, he said, was due to two causes: a low birth-rate and a high death-rate among infants. Physicians could do little to affect the former, but in lessening infant mortality there was an opportunity for work. M. Fournier thought that there was a large and increasing amount of syphilis in France, particularly in Paris. The result of this was sterility or high infant mortality. Among one hundred children born of syphilitic parents sixty-eight died. M. Fournier urges renewed efforts in the prevention of syphilis, and the adoption of some measures to prevent the marriage of syphilitics.

VIVISECTION AGAIN.

Mr. Bergh has again delighted the public with one of his characteristically calm, temperate, and truthful statements regarding vivisection, the occasion being an experimental surgical operation upon the thigh of a sheep. Mr.

Bergh's expressions of opinion are always interesting because he so uniformly succeeds in clothing manifest untruths in a garb of lurid and picturesque rhetoric. Aside from professional artists no one can make statements with so much intense sincerity and feeling. Mr. Bergh now reiterates the view that vivisection is inhumane and useless. There is in this State a liberal and healthful sentiment regarding the utility of vivisection. The medical profession in its view of this matter is strongly supported by public opinion, and we are not obliged at present to take any serious notice of the frenzied and foolish talk of the anti-vivisectionists. Meantime every month strengthens the force of the arguments in favor of experimental medicine.

News of the Week.

THE VALUE OF STATISTICS.—Dr. A. Jacobi, of this city, writes: "I beg to refer at this late date to a notice which appeared on p. 241 of THE MEDICAL RECORD, three weeks ago, but escaped my attention at the time. The writer has not appreciated the courtesy with which the discussion to which he refers was carried on between Dr. Ripley and myself, but informs me that 'it is better to see fewer cases and study them well. In this we are (he is) supported by the fact that the gentleman who saw the fewer cases of croup has drawn the correcter conclusion regarding the effect of the disease upon the respiration.' The writer does not appear to be aware of 'the fact' that an assertion is no fact, that the happy state of mind which induces a gentleman to take his beliefs or convictions for absolute truths, is very enviable indeed, but does not impress others as it does him; and that an apodictic sentence is no proof. I am not aware that, while I still hold that physical law and the observation of *uncomplicated* laryngeal stenosis speak for diminished frequency of respiratory movements in that affection, any new facts or observations have been made public in the few weeks elapsed since the discussion in the Academy of Medicine took place."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—The next Stated Meeting will be held at the New York Academy of Medicine, Monday evening, March 23, 1885, at eight o'clock.

STARLING MEDICAL COLLEGE, Columbus, O., held its annual Commencement March 4th, graduating thirty.

STATE MEDICAL SOCIETY OF ARKANSAS.—The Tenth Annual Session of the State Medical Society of Arkansas will be held at Little Rock, on Wednesday, Thursday, and Friday, April 22d, 23d, and 24th, commencing on Wednesday, at 10 A.M.

THE COLLEGE OF PHYSICIANS AND SURGEONS OF BALTIMORE held its thirteenth annual Commencement on March 13th, graduating one hundred and fifty-five students. The Medical College of Ohio held its sixty-sixth annual Commencement on March 5th, graduating a class of fifty-eight. The Miami Medical College held its twenty-fifth annual Commencement at Cincinnati on March 10th, graduating twenty-seven students. The Baltimore University of Medicine graduated a class of six out of thirteen applicants on March 3d.

THE MEDICO-CHIRURGICAL FACULTY OF MARYLAND holds its annual meeting on March 28th.

THE FOURTH GERMAN CONGRESS FOR INTERNAL MEDICINE will take place at Wiesbaden from April 8th to 11th next. Among the papers and subjects for discussion announced are: "The Treatment of Corpulency," introduced by Drs. Ebstein and Henneberg; "Bronchial Asthma," introduced by Curschmann and Riegel; "Antipyresis," introduced by Filehne and Liebermeister; "Hypnotics," by Liebreich; "New Drugs," by Binz (Bonn); "Surgical Treatment of Asthma," by Hack; "The Movements of the Stomach, Pylorus, and Duodenum," by Rossbach and others. We regret to learn of the recent death of the President, Dr. Frerichs.

THE LATE MR. CHARLES TRACY.—At a special meeting of the medical staff of the Demilt Dispensary, held March 17, 1885, the following resolutions were unanimously adopted:

Whereas, The medical staff of this Dispensary has heard with sincere sorrow of the death of the honored President of the Board of Managers, Mr. Charles Tracy; therefore, be it

Resolved, That, while recognizing in this sudden and unexpected dispensation the hand of an all-wise Providence, we nevertheless fully appreciate the importance to the institution of the loss of its oldest and most distinguished member, its wisest and most experienced counsellor, and its most influential and loyal friend.

Resolved, That we desire to bear the highest tribute to the sterling qualities and the kindly and genial disposition by which the deceased established and endeared himself with all with whom he came in contact.

Resolved, That the distinguished success which attended his labors in this and in the many other charitable enterprises to which, as an officer, his services were so liberally bestowed, was the legitimate outcome of a clear and highly intelligent conception of the duties attending such offices, to which was added a strong sense of the moral obligations which they imposed, and great energy and patience in the execution of their practical details. The finished record of his life, in this relation, is full of valuable suggestion, and will endure as a brilliant example of well-directed usefulness eminently worthy of study and emulation.

Resolved, That the earnest sympathy of the staff be extended to the bereaved family of our late President, and to his fellow-members of the Board of Managers.

Resolved, That copies of these resolutions be presented to the family of the deceased and to the Board of Managers of the Dispensary.

(Signed) JOS. E. WINTERS, M.D.
D. BRYSON DELAVAN, M.D.

THE MEDICAL SOCIETY OF THE STATE OF TENNESSEE holds its fifty-second annual meeting in Nashville, beginning April 14th.

THE MISSOURI STATE MEDICAL SOCIETY meets at St. Joseph on May 12th. Since its last meeting it has become a delegate society.

A STRONG ARGUMENT FOR CONTINENCE.—Extensive and serious adulterations in cubebs are reported.

Charity Hospital, New Orleans.—The New Orleans *Medical and Surgical Journal* gives an interesting account of the work of, and improvements made in, this well-known hospital, which treats nearly 8,000 cases annually. There has been added an annex to the Female Department with a capacity of 83 beds. The Pathological Department, organized under Dr. H. D. Schmidt, had a new dead-house built for it last fall. Of the different diseases treated in the hospital, forty-five per cent. are malarial, or 3,626 cases, with a mortality of twenty-three per cent. Eleven per cent. of all deaths are due to phthisis.

A Prevailing Winter Fever.—There is an endemic fever, with a tendency to an adynamic form, prevailing just at this time over the Western country, says the Kansas City *Medical Index*. It has been variously designated by different observers as "Malarial Fever," "Typho-Malarial Fever," "Typhoid Fever," "Catarrhal Fever," and "Winter Typhoid Fever." The history, symptoms, and course of these cases have in many instances been marked by a distinctly typhoid character, but they have been rather more sudden in their invasion, active in their early febrile symptoms, and more amenable to abortive or modifying treatment.

Typhus Fever appeared in this city this week, being brought by immigrants from Hamburg, where the disease is endemic. Hamburg has been the source of infection before.

Medical Commencements.—The medical department University of Tennessee, graduated fifty-nine students on February 24th; the University of Nashville medical department graduated one hundred students on February 26th; Memphis Hospital medical college graduated thirty-three students at its fifth annual Commencement on February 25th. The Arkansas Industrial University, medical department, conferred diplomas upon eight graduates on March 4th. The McNarry Medical College held its ninth annual Commencement at Nashville on February 27th, graduating a class of nine. The Michigan College of Medicine held its annual Commencement at Detroit on March 2d, graduating a class of twenty-one.

The Bichloride of Mercury in Obstetrics.—Dr. Hulbert, of St. Louis, stated at a meeting of the St. Louis Medical Society, that he had salivated five patients with a bichloride solution (1 to 3,000), given as a vaginal douche twice a day.

Discontent over the Arrangements for the Next International Medical Congress.—It is never possible to please everyone, but in the arrangements for the International Congress of 1887 complete harmony is most desirable. The South and West make a complaint which is voiced by the *Texas Courier-Record* as follows: "The Executive Committee chosen by the Committee on Organization for the Ninth International Medical Congress, is composed entirely of men from the North and East. The entire South and West, and the whole of the continent west of the Mississippi River from Canada to the Gulf, have been utterly ignored in its organization, and not a physician from Chicago, Cincinnati, St. Louis, Denver, Richmond, Kansas City, Atlanta, New Orleans, Austin, nor Detroit, nor Charleston, has been thought of sufficient importance to be named. This is a one-sided arrangement against which we protest, and which the whole medical press should condemn."

A Case Illustrating the Importance of Reading Medical Journals, particularly The Medical Record, is cited by our valued and practical contemporary, the *College and Clinical Record*. A physician in York, Pa., was called to see a child, aged eight, who had swallowed a large shawl-pin. The doctor had been taught to give a brisk cathartic in these cases, but having recently seen an article in The Medical Record on "Pin-swallowing," advising the giving plenty of bulky food, he adopted the suggestion. In forty-eight hours the pin was evacuated in the centre of a mass of fæces.

At the Annual Session of the Académie des Sciences, February 23, 1885, the following prizes were awarded: 1. Prix Montyon, 2,500 francs, to M. Testut, of Nancy, for his "Treatise on Muscular Anomalies in Man Explained by Comparative Anatomy." 2. Prix Montyon, 2,500 francs, to Dr. Cadet de Gassicourt, for his "Clinical Treatise on the Diseases of Infancy." 3. Prix Montyon, 2,500 francs, to Dr. Henry Leloir, for his "Contributions to Tropho-neuroses of the Skin." 4. Prix Godard, to Professor Tourneux, for three embryological and anatomical contributions, viz., upon the "Development of the Uterus and Vagina," upon the "Wolffian Bodies," upon the "Interstitial Cells of the Testicles." 5. Prix Serres, divided between M. Cadiat, for his "Treatise on General Anatomy Applied to Medicine," and M. Kowalewsky, for a "Series of Embryological Studies."

Regulation of Medicine in Texas.—The bill to create a Board of Medical Examiners and to regulate the Practice of Medicine has been reported on favorably by the Senate. The bill to create a Board of Health has been laid on the table.

The Annual Report of the Harvard Medical School for 1883–84 has been presented. Among two hundred and fifty-nine students, ninety-six per cent. spent six terms in attendance at the lectures and other courses. Out of sixty-four applicants for a degree, fourteen were rejected. The record of the school work is in striking, and, to us, painful contrast with that in this city, where some three or four hundred students are yearly turned into doctors after two short terms of lectures.

Dr. C. Flügge has been appointed Ordinary Professor of Hygiene at Göttingen.

What is Truth—in Rhinology, for Example.—A New York laryngologist recommends the use of medicated vapors, powders, and sprays. He uses the spray at a pressure of forty pounds, regards hooking the palate forward as absolutely essential, and holds the tongue depressor himself. Whereupon a St. Louis specialist says that eight to ten pounds pressure is enough, vapors and powders are of no use, and concludes: "If he (the New York laryngologist) used a spray less bunglesome than that of Sass, and knew how to use it properly and would let the patient hold the tongue depressor, he would find no difficulty in getting a strong spray behind the palate without the use of such an instrument."

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 25, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. A. JACOBI presented, in behalf of a candidate, a specimen of *round-celled sarcoma of the kidney.*

DR. R. C. M. PAGE presented a patient who had received

A GUNSHOT WOUND OF THE THORAX.

Robert H. Y——, aged thirty eight, born in Ireland, married, came to this country in 1848 when a child. While lieutenant of infantry in Sherman's army during the late war, he was wounded by a sharpshooter at the battle of Peach Tree Creek, before Atlanta, Ga., July 20, 1864. He was struck near the left shoulder posteriorly, while in the act of turning his head one side to speak to his colonel. A number of military surgeons probed for the bullet, which was fired from an elevated position, but which was never found. He had no hemorrhage from the mouth. He went through various hospitals, but returned to his company the following autumn in time for the famous march to the sea. On this march he was allowed to ride horseback. Since the war he has been a steel letter cutter. He comes of long-lived parents on both sides. Was in good condition with exception of pains occasionally in left breast, near clavicle, up to about one year ago. First had a pain about the middle of his chest one year ago. Suddenly upon a fit of coughing he spit up some blood last July for the first time. In middle of November last he had a return of this, only much worse. Went to Roosevelt Hospital, where he remained about three weeks.

I saw him for the first time this morning at the Northwestern Dispensary (February 25, 1885). Not emaciated, but has coughed steadily now for the past two months. Expectoration has always been white and scant, except during the past three weeks, when it has increased. Still has pain in left breast.

Upon examination I found that the patient had a spot of what I took to be caverno-bronchial breathing, due to dilated bronchus and local consolidation. During the examination my attention was called to the bullet-mark by Dr. Berry, of Japan, who is now in this city. It is probably due to the presence of the bullet.

According to "Holmes' Surgery," and others, we are to regard penetrating wounds of the chest, complicated with the presence of foreign bodies, as always dangerous. The rate of mortality in 484 cases, stated in "The Medical and Surgical History of the War of the Rebellion," was 50.6 per cent. "The foreign body, especially if it be small, such as a bullet, may become encysted and remain quiescent for years. Sooner or later, however, it is liable to become a centre of mischief; the neighboring parts become inflamed; the encysting material breaks down; suppuration takes place; and various symptoms and physical signs more or less resembling those of phthisis pulmonalis present themselves" (Holmes). Arnot reports a case where a piece of hoop-iron was removed from a cyst in the left lung, opposite the third rib, where it had remained fourteen years. The patient was a sailor who was wounded in 1812, and died from inflammation of the lung in 1826. Leash reports the case of a soldier, wounded at the battle of Waterloo, June 15, 1815, in the left breast. He lived forty-two years and four months. The ball was found in a pulmonary abscess, containing about a pint of pus. Velpeau cites a case, mentioned by Guillon, where part of a fencing foil was found in the chest fifteen years after the infliction of the wound. One end of the piece of foil was implanted in the rib, while the other end was fixed in the spine: the middle part was in the centre of the lung, surrounded by calcareous deposit. There was no suspicion of the presence of this foreign body during life. Sometimes, as in case of bullets, the foreign bodies ulcerate into the bronchi and are coughed up. Two such cases are related in "Gross' Surgery," and numerous examples of this are given in "The Medical and Surgical History of the War of the Rebellion." "Bronchitis, pneumonia, pleurisy, and phthisis," according to Holmes, "may all arise in consequence of, or in association with, the retention of foreign bodies in the lungs and air-passages during prolonged periods. It is uncertain at what period danger may become imminent, and in what way it may arise.

THE PRESIDENT asked Dr. George F. Shrady concerning his experience in the treatment of gunshot wounds of the chest in army hospital practice.

DR. SHRADY said that in the majority of cases the patients recovered. A great deal depended upon the fact whether or not clothing or other foreign substance had been carried in.

THE PRESIDENT remarked that when a rib was shattered at the entrance of the ball there was no case on record of recovery; but that when a rib was shattered by the ball on making its exit the prognosis was not so unfavorable.

CARCINOMA OF THE BLADDER, WITH SECONDARY GROWTHS IN THE URETER, KIDNEY, RETRO-PERITONEAL GLANDS, INTESTINE, PANCREAS, SPLEEN, LIVER, AND LUNGS.

DR. WILLIAM HENRY PORTER presented specimens with the following brief history. They were removed from a male, fifty-two years of age, who first came under observation during the fall of 1884, when he complained of pain in the left lumbar region radiating down the line of the ureter to the bladder. There was some difficulty in micturition with evidence of urethral stricture. The patient was admitted to the Presbyterian Hospital under the care of Dr. A. C. Post. The urethral stricture was relieved by an operation, following which the pain and difficulty in voiding the urine disappeared and the patient's general condition improved.

After a few weeks the symptoms were reversed; the pain returned, the patient progressively emaciated and grew weaker. A week or two prior to his death Dr. Edward S. Garner, the house surgeon, was able to make out a distinct tumor in the abdomen, located upon the left side between the umbilicus and free border of the chest-wall. It appeared to extend under the free border of the ribs. From which organ the neoplasm sprang could not be made out during life. The urine was examined and nothing abnormal detected. The patient progressively declined. Four days before his death he suddenly developed suppression of urine. Diuretics were given, also hydrogogue cathartics; dry cups were applied to the lumbar region. The bowels moved freely, but suppression continued. No active symptoms of uræmia were developed. The patient's mind was clear. At the end of the fourth day of the suppression he attempted to sit up in bed and dropped back dead.

Necropsy, by Dr. Garner, forty-eight hours after death. —Heart small and flabby, weight ten ounces (283.495 grammes). Both lungs were firmly bound to the chest-wall and diaphragm. The superior lobes, especially at the apex, were the seat of syphilitic interstitial thickening. The inferior lobes were less involved and almost gangrenous. Throughout this indurated and partially necrotic mass there was a number of small white nodules. The bronchial glands were enlarged and indurated. The nodules in the lungs and glands were the seat of carcinomatous deposits. Abdominal cavity: In the left lumbar region there was a large retroperitoneal neoplasm, which was found to be principally a growth involving the glands, and secondarily the kidney, spleen, pancreas, and intestines. The spleen was small and soft, except at the point where the new growth had invaded its tissue. Weight six ounces (150.372 grammes). Genito-urinary tract: The left kidney lay against the retroperitoneal neoplasm. The new growth had invaded

the renal pelvis and all that portion of the kidney adjacent to the sinus renalis. More than one-half the kidney had been destroyed and replaced by the carcinomatous tissue. The ureter from kidney to bladder on the left side was also indurated. To the inner side of the ureter and close behind the bladder there was a large neoplasm about the size of a horse-chestnut; this was composed largely of fibrous tissue. The bladder was contracted and congested, its interior was covered by villous projections; this was probably the primary origin of the carcinoma. The right ureter and kidney were not invaded by the new growth. The right kidney was hypertrophied, and twice its normal size. The epithelial cells had undergone the parenchymatous infiltration common in wasting diseases. The liver was also the seat of numerous secondary deposits, encephaloid in character. The organ was a little fatty, weight eighty ounces (2,271.632 grammes).

The case was interesting, in that carcinoma of the bladder is not common, from the number of organs secondarily involved, on account of the long continuance of the suppression, and the sudden death from cardiac paralysis without any premonitory uræmic symptoms.

PYELONEPHRITIS.

Dr. Porter also presented a specimen from a patient in the service of Dr. A. H. Smith, at the Presbyterian Hospital, with the following history: The patient was a female, thirty-five years old. About the middle of the month of November, 1884, she had an attack of acute cystitis; under treatment she gradually improved until the middle of December. From that time she was up and around, apparently as well as ever. About the middle of January, 1885, she commenced to have repeated chills and an irregular fever. A diagnosis of intermittent fever was made, and for that she was treated with quinine. She, however, grew steadily worse and developed pain and tympanites in the abdomen.

When admitted to the Presbyterian Hospital she gave the above history and said that her bowels had been constipated. This statement was contradicted by her husband after her death, who said that she had suffered from diarrhœa. The previous history at least was very incomplete. While in the hospital the temperature continued irregular, and she had several rigors and a peculiar sweet and pyæmic breath; there was also nausea and vomiting. The abdomen was quite painful and tender, especially upon the right side and near the free border of the ribs just internal to the axillary line. There was marked tympanites with constipation. The urine was examined and found to contain albumen and casts. The diagnosis of peritonitis and Bright's disease was made and internal suppuration strongly suspected. She was only in the hospital about twenty-four hours before her death.

The *necropsy* was made twelve hours after death by Dr. Henry Rolando, house physician.—Body not emaciated. Thoracic cavity: Heart normal; lungs normal, œdema and congestion excepted. Abdominal cavity: No evidence of a diffuse general peritonitis; the left side was normal and free from pus and lymph; the right side was the seat of a rapidly extending peritonitis. There was a large tumefaction in the region of the right kidney, and on lifting up the right lobe of the liver pus was found free in the peritoneal cavity. The small intestines on the right side and the cæcum were covered with fibro-plastic exudation. The small intestine lodged in the pelvic cavity was congested and covered with inflammatory exudate. The pouch of Douglas contained a little pus. The inflammation would have soon invaded the whole abdomen. The chief lesion was in the genito-urinary tract; the right kidney was surrounded by a fibro-plastic inflammatory capsule and by it bound firmly to the inferior surface of the liver. This mass was removed and then bisected in the usual manner for opening the kidney. The interior which should have contained a kidney was one mass of purulent pockets and necrotic renal tissue. Nothing that could be recognized as a renal pelvis could be found, a few strips of nephritic tissue still remained, which was all that remained to represent a kidney. A small pocket of pus in this capsule had ruptured into the peritoneal cavity and was the cause of the peritonitis. The opening of the right ureter into the bladder was apparently closed. A bronchotome, however, was easily introduced into the site of the opening and passed into a dilated ureter. The ureter was dilated throughout its whole extent, the diameter of which ranged from one-third to one-half of an inch; its wall was extensively ulcerated and the seat of numerous pockets of pus. The opposite kidney was the seat of a chronic parenchymatous metamorphosis of the epithelial cells. There was no evidence of a pyelitis or pyelo-nephritis on this side. The bladder was a little congested. There was a striated appearance radiating from the opening of the right ureter. The opening of the opposite ureter was normal. There was no urine or pus in the bladder, but it was empty at the time of the necropsy. The liver was fatty.

This specimen was of interest in that it showed a typical sample of pyelo-nephritis, the rapidity with which the disease may progress, and the difficulty of diagnosticating the disease when the urine does not contain a macroscopic quantity of pus. Also in contrast with the next specimen, or true surgical kidney.

ENLARGED PROSTATE, CYSTITIS, SUPPURATIVE EPIDIDYMITIS, SUPPURATIVE AND SLOUGHING ORCHITIS, AND MULTIPLE NEPHRITIC ABSCESSES, OR TRUE SURGICAL KIDNEY.

Dr. Porter also presented the above specimens from a patient in the service of Dr. George F. Shrady at the Presbyterian Hospital, with the following history: The patient was a male, aged sixty-three, who had been suffering for some time past with an enlarged prostate and concomitant cystitis. About two weeks before admission to the hospital he had an attack of retention of urine. The bladder was entered with difficulty. A considerable time was occupied, and a good deal of irritation produced by the introduction of the catheter. The damage done excited a suppurating epididymitis and orchitis, with sloughing of the latter. On account of this he was admitted to the hospital. Non-irritating diuretics and hydrogogue cathartics were given. As a result his bowels moved freely, and he voided his urine in small quantities and at short intervals, and passed about twenty ounces (620 c.c.) per day. Physical examination gave every evidence that the bladder completely emptied itself. For this reason and the fact that the previous introduction of the catheter had caused so much irritation and inflammation, it was not re-introduced while in the hospital. He was apparently improving until the third night after admission, when he suddenly developed œdema of the lungs and died.

The *necropsy* was made twelve hours after death by Dr. Hunter Pope Cooper, the Assistant Surgeon.—Body very thin. Thoracic cavity: Heart normal; weight, 12 ounces (240.194 grammes). The lungs were firmly bound to the chest-wall by old pleuritic adhesions; both organs were congested and œdematous; the dependent portions gave marked evidence of hypostatic congestion Weight of left, 24 ounces (680.388 grammes), of right lung, 26 ounces (737.078 grammes). Abdominal cavity. Upon opening the abdominal cavity, the bladder was found to contain fluid, and extended about four inches (9 centimetres) above the symphysis pubis. At the summit of the bladder there was a tit-like projection or vesical sacculus. The gall-bladder was enormously distended, and at the time of the necropsy the two bladders were in contact. Had this condition existed during life it would have been impossible to have determined positively by physical examination whether the urinary bladder was over-distended or not. The spleen was enlarged and firm, and at one side of it there was a supernumerary

spleen. Weight of both, 12 ounces (340.194 grammes). Kidneys: Both organs were enlarged and the seat of chronic parenchymatous metamorphosis. In both numerous small abscesses were commencing to form, which were multiple and about the size of a large pin head. This condition was the early stage of a suppurative nephritis or true surgical kidney. The pelvis and ureters were slightly dilated, and contained some urine which was a little purulent. Weight of the right kidney, 7 ounces (198.446 grammes); of the left, 6 ounces (170.097 grammes). The urethra was apparently normal at the posterior inferior wall. Just in front of the prostate gland there was quite a pocket, into which the catheter went instead of into the bladder. The prostate was somewhat enlarged, and the middle lobe was crowded upward and forward into the cavity of the bladder. This pushed the mucous membrane forward, so that together with the middle lobe it formed a "bar" at the neck of the bladder and occluded the outlet, in this way it acted like a ball-valve, and decidedly interfered with the escape of the urine. As a result, the wall of the bladder had become hypertrophied, and the superior two-thirds was decidedly fasciculated; at the summit near the attachment of the urachus, or suspensory ligament, there was one large vesical sacculus, or appendix vesicæ. There were several places where a similar condition was commencing to form. The bladder contained sixteen ounces of urine containing pus and blood. The epididymis of the left side was the seat of a diffuse suppuration; the left testicle was in a similar condition and had commenced to slough. The liver was slightly fatty. No gall-stone could be found to account for the enlarged gall-bladder.

This case was of interest in showing how a slight enlargement of the prostate might cause a protrusion forward of the mucous membrane, and decidedly dam back the urine; how the forced introduction of the catheter may excite extensive suppurative inflammation of the whole or any portion of the genito-urinary tract, and also in comparison with the other two specimens, illustrating three different and distinct lesions of the urinary tract.

The three cases evidently died from the same cause, uræmic poisoning, but all were free from the active convulsive or comatose symptoms. They are, therefore, interesting in showing that uræmia or a form of blood-poisoning from retained effete material may be the cause of death by cardiac paralysis alone, or in conjunction with œdema of the lungs, without any marked premonitory warning.

Dr. T. Mitchell Prudden presented a specimen of

PRIMARY HYDROCEPHALUS IN AN ADULT.

The case occurred in Dr. A. B. Ball's service, in Bellevue Hospital, and for the clinical history he was indebted to the house physician, Dr. A. Brothers:

Carlo B——, about forty years of age; occupation, stand-keeper; nativity, Italy; married man; powerful build; admitted February 12, 1885.

History.—Patient was never sick before in his life. No family history to be obtained. Has two children alive and well. Denies a specific history. Well-marked alcoholic history. Has been a hard-working man, being out of bed each day by 4 A.M., and never retiring before 12 at night. Five weeks before admission began to suffer from an intense headache, referred to frontal region. Took a mustard foot-bath, and from that time has been unable to stand or walk. About the same time his memory began to fail him, and he became somewhat deaf. During the past five weeks he has been confined to bed. His mind has been clear. Loss of memory and deafness have become steadily worse. Headache has been more marked at certain times, and entirely absent at others. Rigidity of the body and condition of apathy persisted up to admission (history obtained from friends). No injury.

On admission.—Temperature, pulse, and respiration normal. Patient complains of nothing. Lies in stupid condition. Hearing seems to be affected (blunted). Pupils are unequally dilated. Some conjunctivitis. Swallows easily. Slight cough and evidences of bronchitis. Patient unable to sit up or stand. If stood up out of bed there is extreme backward rigidity of the entire body from head to foot. No tenderness over spinal column. No paralysis. Sphincters normal. Faradic contractility normal. No disturbances of sensation. Tendon reflex exaggerated. Mind occasionally wanders.

Diagnosis.—The different spinal troubles were excluded. Symptoms seemed to point to pressure on brain, due probably to tumor situated in region of cerebellum.

Treatment.—Iodide of potash pushed to one-drachm doses t. i. d.

Progress of case.—Patient continued in condition of stupor alternating with periods of slight delirium, and finally passed into complete coma, in which he died. On February 16th his temperature suddenly rose to 103°, and consolidation of lower lobes of both lungs was made out. He developed paralysis of muscles of palate and pharynx, but this was only temporary. Rigidity of body gradually disappeared. Urine was passed involuntarily. Bowels only moved after enemata. During last four days he lay in comatose condition, with temperature ranging between 100½° and 103¾°. He died on February 22, 1885.

Autopsy.—Man large, well built, and fairly nourished. Dura and pia mater appear normal. Convolutions not flattened. On the removal of the brain from the skull the corpus callosum was burst through and there was an escape from the lateral ventricles of about from four to five ounces of clear serum. The cerebral arteries were normal; corpus callosum somewhat thin; lateral ventricles widely dilated; ependyma not thickened and not roughened, but the blood-vessels were somewhat dilated. The other ventricles appeared normal. Brain tissue not dry and contained about the usual amount of blood. Cerebellum normal. I could find no evidence of lesion in the veins of Galen, nor did the communications between the fourth and other ventricles present any abnormalities.

In the absence of any evidence of inflammatory processes either of the meninges or ependyma, or interference with the veins or interventricular passages, this would seem to belong among those rather rare cases of primary hydrocephalus in the adult whose cause is not evident.

A considerable number of cases similar to this have been described; several by Abercrombie, some by Gintrac. They are not usually distinguished. Delafield, in his lectures, makes a separate class of them, some being with and others without evidences of ependymitis. According to his description of the clinical history, they are very apt to go on for a time with no, or obscure, cerebral symptoms. These symptoms may more or less suddenly become pronounced, and the death of the patient follow within varying periods, but sometimes within a short time. The symptoms in the later stages of the disease are apt to be in general either those of cerebral apoplexy or of meningitis, and may be more or less well pronounced. At the autopsy, however, lesions similar to those in our specimen are alone found.

The heart and large vessels were normal. In both lungs there was acute purulent bronchitis, and in both lower lobes well-marked general broncho-pneumonia with a moderate amount of consolidation about the bronchi. These lobes were also deeply congested. Kidneys showed a moderate amount of chronic diffuse nephritis. Other viscera normal.

(To be continued.)

Thallin, the new Antipyretic, is found by Dr. C. Alexander to be better than kairin, but not so active as antipyrin, over which latter it has only the advantage of smaller dosage and more agreeable taste.

Correspondence.

OUR LIVERPOOL LETTER.

(From our Special Correspondent.)

PRACTICAL POINTS ON AMPUTATIONS—ETHER AS AN ANÆSTHETIC—THE USE OF ANTISEPTICS—THE QUESTION OF EXCISION—TREATMENT OF NON-UNION IN FRACTURES, OF HERNIA, STRICTURE OF THE URETHRA, AND JOINT DISEASES.

LIVERPOOL, March 4, 1885.

Most American physicians who visit Europe land at Liverpool, and of these a large proportion take the opportunity of visiting the medical institutions of that city. Many of your readers have, therefore, doubtless visited the largest of the hospitals, viz., the Liverpool Royal Infirmary. As a school of medicine Liverpool is decidedly a rising one, and has lately improved its position by becoming affiliated to the Victoria University, Manchester. It numbers among its teaching staff many who have attained more than a mere local fame. Among these the following names at least are not unknown in America: A. T. H. Waters, Reginald Harrison, Mitchell Banks, Bickersteth, and Rushton Parker. These are all surgeons, with the exception of Dr. Waters, who is Senior Physician to the Royal Infirmary and Past President (1883–84) of the British Medical Association.

It is of Liverpool surgery that I now propose to speak. This article has been suggested by a recent perusal of a small work in pamphlet form recently issued for private circulation by Mr. Mitchell Banks, Surgeon to the Royal Infirmary. It is headed "Clinical Notes," and is virtually a statement of two years' surgical work in Mr. Banks' wards. It is, however, very different to the ordinary cut-and-dried hospital records, and contains a good deal of really interesting and informing material. Mr. Banks expresses his opinions on most of the subjects to which he adverts, although he modestly says the remarks he has printed "are only intended for the amusement of my friends and such as feel an interest in the work done at the Liverpool Royal Infirmary." I found myself so much interested in Mr. Banks' epitome of Liverpool practice that I began to make a few notes on the same in hopes that they might interest your readers. I have added a few remarks here and there as to the practice of other British surgeons, more particularly with reference to surgical practice in the metropolis.

Speaking of amputations, Mr. Banks naïvely remarks that for his part he only knows and only teaches two things about them, viz., to make one flap longer than the other and to saw the bone as low down as possible. I may remark that the size of the flaps is a question on which surgeons differ greatly. Many British surgeons are now in favor of having two flaps of nearly equal size. The "circular" method has also many advocates.

In amputating through the femur for disease of the knee-joint it is difficult, says Mr. Banks, to see any use in keeping the patella. Sawing off its cartilaginous surface and then trying to make it stick on to the cut end of the femur may afford an operator of a mechanical turn of mind some amusement, but nothing more. It is not the patella we want, but the hard skin over it.

Boneing the great toe is suggested as an improvement on amputation or excision of the metatarso-phalangeal joint when the latter is diseased.

In describing a case of double amputation for railway injury, Mr. Banks alludes to rapidity of operating as an element in prognosis. In this case the patient, a boy of ten years of age, had fallen from a train and lay in a tunnel all night in severe wintry weather. He was apparently dead when brought to the hospital, but some signs of life appeared after a time. Subcutaneous injections of ether were given him (two of thirty minims each) and "he was placed on a mattress opposite a large fire and literally cooked into life again." Reaction had fairly set in by the evening. He was then taken into the theatre, "the smallest whiff of ether" given him, while the two injured limbs were removed "with all the rapidity possible." Rough dressings of lint soaked in carbolized oil were applied, and the patient "was again in the ward on the mattress before the fire in less than fifteen minutes from the time of his removal." Space fails me to give the full history of this most interesting case, but I may say that the patient was attacked with "surgical scarlet fever," the urine became albuminous, the flaps opened up and refused to heal, and the bones protruded. The patient eventually recovered, a result largely due, Mr. Banks believes, to the speed with which the operations on him were performed. He remarks that in these days of anæsthetics the surgeon is apt to proceed too deliberately, forgetting that the patient, though not suffering pain is suffering shock—that "every minute of anæsthesia, every fresh incision, every lost teaspoonful of blood," lessens his chance of recovery. Mr. Banks goes so far as to say that in a thigh amputation for smash, the fact of the patient being on the table twenty minutes in one case, or forty-five in another, makes all the difference "between his crossing the bar and sticking on it." In the case just alluded to, the warm fire, subcutaneous injections of ether, the selection of ether as an anæsthetic, and the careful use of antiseptics, all no doubt aided in procuring the favorable result.

Mr. Banks is a warm advocate of ether as an anæsthetic, and even goes so far as to say, "To-day it has elbowed chloroform out of the field." This may be so in Liverpool; it certainly is not so in London. Chloroform is still largely used both in hospital and private practice. The A. C. E. mixture is becoming more generally used also. Local anæsthesia is becoming more largely employed. Ether-spray, or ice and salt, is much more often made use of for minor operations than formerly. The introduction of cocaine has stimulated investigators to try and discover some other local anæsthetizing agent. Mr. Banks recognizes two objections to ether. One, the danger of excessive secretion of mucus in bronchitic patients; the other, its failure to thoroughly control muscular action even after feeling is abolished.

Listerism finds an earnest advocate in Mr. Banks. He narrates a case of amputation for injury in which the right foot (from which some toes had to be removed) began to slough, and a condition closely resembling hospital gangrene set in. The leg amputation close beside it healed (under its antiseptic cover) without a trace of suppuration. If, in the face of natural experiments such as these, says Mr. Banks, people still sneer at Listerism as a fad, further argument with them is futile. I may remark, in passing, that Mr. Banks' surgical colleagues are at one with him on the antiseptic question.

Mr. Banks has some very thoughtful remarks to make on the subject of excisions. At the International Medical Congress in London (1881) Mr. Howard Marsh ignored statistics and pointed out that excision belongs to the same class of treatment as amputation. It is giving up the attempt to cure the disease. To this view Mr. Banks cordially assents. Far better than advocating early excision is it, he says, to devote ourselves to teaching the early recognition of hip and joint disease. "The children of rich people," he says, "don't have their hips and knees excised. Why not? Because the articular mischief is promptly found out, and skilfully and patiently treated." Joint diseases are so prevalent in the cold and damp climate of Liverpool, that Mr. Banks' opinion is worth hearing at any rate. I may remark that the Clinical Society's report (1881) on excision of the hip-joint, showed a mortality of thirty-five per cent. in cases of excision as against thirty in cases of suppuration treated by rest and extension.

Mr. Banks says the following is his teaching to students: "In children up to fifteen years of age, if you get a case of knee or hip disease from its commencement, make up

your mind to save the limb. You ought to save it. Between fifteen and twenty-five, failure is to be looked for very often, and then you may excise. Don't operate until your art is exhausted—only don't wait until your patient is exhausted. Fortunately after twenty-five or thirty, joint mischief is not common; but at that age whatever you may do with the hip, do not excise the knee, if your patient will let you amputate."

Mr. Banks says that his impression of excision of the knee-joint after thirty years of age is that it is, as a rule, disastrous, and that many a life has been lost to save a leg. On this question many surgeons will be disposed to join issue with Mr. Banks, but one remark that he makes is certainly worth remembering. It is that a workingman does not usually do a stroke of work on an excised knee-joint under eighteen months or two years; after amputation he is at work in from four to six months on a sound stump.

Thomas' knee splint is *the* method of treatment for fractured femur at the Liverpool Royal Infirmary. Mr. Banks says he now uses it for all fractures in the middle and lower thirds till close upon the condyles; for fractures in the upper third he prefers the "MacIntyre." For fractured patella, opening the knee-joint and wiring the bony fragments together finds no acceptance in Mr. Banks' eyes as a method of treatment. He remarks that such a proposition savors of surgery run mad. I can testify that Mr. Banks is not alone in this opinion. Many metropolitan surgeons are of much the same opinion, though the adverse criticisms which were expressed on Lister's first case are now somewhat modified in tone. Mr. Banks says that if he should be unfortunate enough to break his patella, "nothing in the world" shall induce him to have his knee-joint laid open so long as he can "get hold of a Thomas knee splint and a yard of sticking-plaster." Where a limb has become useless, says Mr. Banks, then Sir Joseph Lister's proceeding is not only justifiable but necessary. But useless limbs ought not to occur. We so frequently see such bad results because the surgeon, after having kept his patient in bed six weeks or two months, proceeds deliberately to bend the joint. The joint should be kept from bending for eight months, says Mr. Banks, viz., two months in bed and then six months out of bed with a splint on. "Let him get up and be fitted with a Thomas calliper splint, clipping into the sole of his boot, and he can go about his business as well as ever, unless he be in the acrobatic line. It will be far cheaper for the hospital to fit him up with this splint and give it to him, than to have to take him in six months afterward for the purpose of having his joint opened and his patella wired." As for the joint getting stiff, that is a fallacy, unless there has been inflammation in it or the surrounding structures.

In some cases of non-union of fractures Mr. Banks has found good results from taking all splints off and allowing movement to occur. The orthodox treatment of maintaining absolute immobility sometimes fails, he believes, through not causing sufficient irritation for callus to be thrown out.

A large section is devoted to tumors, simple and malignant. In removing malignant tumors he lays great stress on the importance of removing the nearest glands in all cases, *whether enlarged or not*, though even then he regards recurrence as almost certain unless the disease be attacked early. As to the danger incurred from extensive operations Mr. Banks regards that as imaginary. He has performed most formidable and extensive operations with success (so far as the operation was concerned) in cases of malignant tumors. But where the disease is already very extensive, he regards recurrence as certain. He says: "As for extensive removals for extensive diseases, I find, on looking over my hospital records for eight years, that I have only succeeded in saving one solitary patient."

Distinctly malignant sarcomata he regards as hopeless, a melancholy opinion shared by many other British surgeons.

Several cases of resection and union of divided nerves are narrated; also two remarkable cases of locomotor ataxy in which improvement—in one case considerable in extent—followed stretching of the sciatic nerve.

Several interesting cases of hernia occurred. When, on the sac of a hernia being opened, the bowel is found gangrenous and obviously unfit to be returned, Mr. Banks says his opinion is that the bowel should be slit open and stitched to the lips of the wound, and *that the ring and surrounding parts should be left absolutely untouched.* "The intestine," he says, "should be cut into as if it were an abscess. By the time matters have come to such a pass that the gut is dead, the ring will almost certainly be glued around its neck by adhesive lymph, and the abdominal cavity quite shut off from the hernial sac and its contents." The resulting artificial anus can be easily cured afterward. One case was very successfully treated by introducing a thick piece of india-rubber tubing into the opening, and pushing one end up the ascending bowel, and the other down the descending. The fæces were liquid and passed through the tube. The pressure of the elastic tube gradually wore away the "spur."

Mr. Banks does not defend his plan as a scientific procedure, but he says: "In private or in country practice, where hernias are often cut at night, and with but scant help, I suspect that the plan of cutting open the bowel and letting everything alone will hold good for many a day to come." He is rather doubtful of the advantages of abdominal section in cases of intestinal obstruction. Many apparently hopeless cases have recovered without operation; in many cases in which the abdomen has been opened some condition has been found which it was impossible to relieve. Mr. Banks believes that "the operation of the future will be ileo-laparotomy, where a small abdominal incision is made, and the first piece of distended intestine brought to the surface and opened. This is not a dangerous proceeding; it gives time for nature to act, if she can; and the resulting artificial anus is readily curable if the patient recovers."

Mr. Banks is no friend to gastrostomy when performed for malignant œsophageal disease. "So long as a man can swallow milk and strong beef-tea through his stricture, he is as well off as if he were getting it through a hole in his stomach. When he can no longer do this his time has come. It is far more merciful to give him plenty of morphia, and let him die in peace, than to torment him with a surgical operation which can only preserve life for a brief period under the most distressing circumstances to himself and all around him."

An interesting section is devoted to stricture and urethral fistulæ. Mr. Banks believes firmly in gradual dilatation, and with the metallic bougie. He is not alone in his preference for "metal," but the preponderance of opinion at the present day in England is certainly largely in favor of "rubber." Hospital teachers in London mostly recommend the use of the soft bougies. Since they have been more commonly used, patients with whole series of false passages are less commonly met with; in fact, they are now a rarity. Holt's operation is favorably mentioned. Otis' views on the calibre of the urethra receive due recognition.

Mr. Banks has very clear views on joint and bone diseases. He says, and justly: "My recollection of the treatment of joint diseases in the Edinburgh Royal Infirmary, when I was a student there more than twenty years ago, is that the whole thing was a farce. There really was no treatment, as we understand it nowadays, and the result was that the surgeon groaned aloud at the mere sight of a hip or knee case. The principle of rest was just beginning to lay hold of men's minds, but they did not completely grasp it." Complete immobility is the grand desideratum for a diseased joint, and the teaching of the Liverpool school is that the only means of obtaining this perfectly is by means of the "Thomas" splint.

One grand advantage of applying it is, that the patient can walk (from his pelvis), and is thus not confined to bed and debarred from fresh air and sunshine. Mr. Banks has seen benefit from the actual cautery. The actual cautery also finds favor in some of our London hospitals. I have seen remarkable benefit accrue from it in cases of chronic disease of the spinal column, also in affections of the cord.

Sayre receives no scanty praise from Mr. Banks. As Thomas' splint is to knee-joint, so is Sayre's jacket to Pott's curvature. "They have," says he, "raised these maladies from the pit of almost utter hopelessness to within a measurable distance of cure." Many British surgeons will endorse this. In many cases where it does no good it is because it is not properly applied. Either the surgeon does not do it himself, and leaves it to the instrument-maker (I have known this to be frequently done), or else he does apply it himself, but does not take the trouble to do it properly. The same remark may be made of Sayre's jacket as of the use of antiseptics, viz., that large numbers of practitioners who use them do not take sufficient pains to carry out the system efficiently.

Many other incidents of Liverpool practice are worth recording, but I have already exceeded my space. I must just mention, in concluding, "bursal" affections, which seem tolerably common in Liverpool. Mr. Mitchell Banks emphasizes the importance of the early recognition of suppuration in the olecranon bursa, its danger when it does occur, and the importance of treating it at once by incision (under anæsthesia) from end to end.

OUR PARIS LETTER.

(From our Special Correspondent.)

TRANSMISSIBILITY OF TUBERCULOSIS BY VACCINE LYMPH—INFLUENCE OF THE ANTISEPTIC METHOD ON ERYSIPELAS—THE DEPOPULATION OF FRANCE—THE PREVALENCE OF ABORTIONS AND INFANTICIDE.

PARIS, March 6, 1885.

THE question of the transmissibility or non-transmissibility of tuberculosis by vaccine lymph was lately brought before the Medical Society of Hospitals, when Dr. Strauss gave an account of the researches made by him during the last two years, in view of deciding the above point. It will be recollected that, in 1881, M. Toussaint, in a note communicated to the Academy of Sciences, stated that he vaccinated a phthisical cow from a healthy child; he afterward inoculated a pig and a rabbit from the vaccine pimples of the phthisical cow, and both animals were attacked with tuberculosis, but Koch's bacillus was not found in the lymph. Dr. Strauss repeated these experiments, and he stated that in the space of eighteen months five phthisical patients were successfully revaccinated in his hospital wards, but no bacilli were found in the vaccine pimples. Inoculations from the vaccine lymph of phthisical patients were practised in the anterior chamber of the eyes of rabbits, but they also afforded absolutely negative results. These five negative cases are confirmative of the four cases related by M. Lothar Meyer, of Berlin; and M. Chauveau, of Lyons, following in the same line of researches, arrived at the same negative result in twenty-two cases that he had observed. Dr. Vaillard stated that he had inoculated the vaccine lymph of certain tuberculous patients into animals, but with the same negative results as those obtained by Dr. Strauss. There would, therefore, be twenty-six negative cases opposed to the only positive one of M. Toussaint, and Dr. Strauss considers himself justified in concluding that tuberculosis is not transmissible by vaccination. Moreover, the age of the vaccine subjects would be sufficient guarantee. As for heifers or calves, these are still more rarely tuberculous than children.

Professor Verneuil read a paper last week at the Academy of Medicine on the influence of the anstiseptic method on the genesis of erysipelas so common in surgical wards, and he thinks that if Listerism be rigorously carried out this dreadful complication will completely disappear after operations. M. Verneuil considers that the antiseptic method exercises its beneficial influence not only on the patient himself, but on the atmosphere of the ward, on that of the entire hospital, and even on the neighborhood outside the hospital.[1] M. Verneuil bases his thesis on the small number of cases of erysipelas that have occurred during the last few years at La Pitié Hospital, of which he is surgeon, and on the small number of admissions into the medical wards from spontaneous erysipelas, which is evidently due to the improved sanitary condition of the quarter in which the hospital is situated. But, it may be asked, whether the diminished number of cases of erysipelas in the hospitals may also not be attributed to the improved sanitary condition of the quarter. M. Verneuil's faith in the antiseptic method is such that he considers, if properly carried out, erysipelas, like pyæmia and hospital gangrene, will become more and more rare until they disappear altogether. M. Gosselin, and other members present, were of the same opinion, but, by a strange aberration of temper, M. Le Fort thinks that, contrary to the opinions expressed in favor of the use of carbolic acid, a great number of cases of traumatic erysipelas may be attributed to the introduction of that substance into hospital practice. The debate on the subject has not been closed but will be resumed at the next, and perhaps one or more of the subsequent meetings of the Academy.

By way of variety subjects of minor importance are brought on the tapis, but these are eclipsed by the great debate which has been going on for some time, on the depopulation of France, and which is justly occupying the attention of the ruling powers. I shall not here enter particularly into the causes that have been assigned for the diminishing population, as they have been published in the bulletins of the Academy of Medicine and other medical journals. I may, however, refer to them in a general way. These are: A voluntary abatement of fecundity, abortions criminal or otherwise, still-births, Malthusianism, infanticides, infant mortality from "natural causes," etc. Various causes have been advanced to account for the great diminution in the vitality of infants and the great increase of mortality among them, but according to Professor Fournier, the well-known syphilographer, the most potent cause is syphilis, which he says is much more prevalent in all ranks of society than is generally supposed. In taking the most favorable cases, that is from private practice, where syphilis causes less ravage than among the poorer classes, because among the upper classes better care is taken:

In 403 cases in which the father alone was syphilitic, the mother being unaffected, there were 115 deaths or a little more than 1 death to every 4 births. If the father and mother are syphilitic, the mortality becomes frightful. A syphilitic woman, cited by M. Fournier, had 11 miscarriages in 10 years; after this she gave birth to a child at full term but syphilitic. Another woman, observed by Dr. Ribemont, had 19 pregnancies, and 19 deaths. Syphilis then can soon destroy whole families, and this case is frequent.

Of 208 pregnancies observed in his private practice, and in taking women at different stages of syphilis, M. Fournier found only 60 children born alive, and the other 148 were either premature or still births. At the Lourcine (hospital for syphilitic females), to which he was attached for more than seven years, M. Fournier found 56 deaths out of 100 pregnancies. At the St. Louis hospital, of which he is at present physician, he found the difference in the proportion very slight: 225 deaths out of 248 pregnancies. To avoid being accused of pessimism, M. Fournier quoted the statistics published by other authors. These statistics give 77 deaths to 100 cases,

[1] This is surely a great deal more than Lister himself would expect.

which figures are very nearly the same as those obtained by M. Fournier.

Thus it will be seen that the evil is great and telling on the population, a fact easily established, but it is much more difficult to find a remedy. M. Fournier, however, suggests that to reduce the mortality from this cause to a minimum we should: 1, better defend ourselves against syphilis; 2, we should treat it better; and 3, we should be more severe than is generally the case as regards marriages among syphilitic subjects, and he concludes with the following salutary advice that no syphilitic patient should be allowed to marry before having undergone three or four years of proper treatment.

OUR VIENNA LETTER.

(From our Special Correspondent.)

NOTHNAGEL ON THE USE OF DIGITALIS IN VALVULAR DISEASES OF THE HEART—THERAPEUTICS OF ACUTE ARTICULAR RHEUMATISM.

VIENNA, February 28, 1885.

THE following are the points made by Professor Nothnagel, in a late lecture, concerning the use of digitalis in heart lesions: In the first place, said the professor, it is necessary for the proper consideration of the treatment of the disease to keep steadily in view the fact that valvular lesions, as such, after they are once present, are irreparable, and the treatment is to be directed to the result arising from the failure of the valves, and not particularly to the lesion itself. As is well known, up to a certain stage of the disease, these lesions are compensated for in various pathological ways. No active treatment is necessary until symptoms of a disturbance of this compensation present themselves. During this stage absolutely no remedies are of use, and, in fact, often do harm if given. When, however, the weakening of the hypertrophied heart-muscle, from overwork or other causes, sets in, and symptoms of compensation disturbance occur, certain means are at our disposal to avert the threatening result: 1, By the rest of the organ, patient in bed, etc.; 2, by special remedies to strengthen the weakened muscle.

First and most prominent of these medicines is digitalis. In England and America, at the present day, it is given in a multitude of different heart affections and different diseases, expecting many results, according to its many separate physiological actions as given in the English books. In the Vienna school such universal and illogical use of the drug is not made. As an antipyretic digitalis should *never* be employed. Its action as such, when used simply to obtain a reduction of temperature, is too slow, and this result comes too late to be of service. It might be permissible, perhaps, to give it where the temperature was due to the heart. Digitalis, however, is especially to be given with regard to its action on the heart. This drug, as proven by the experiments which Professor Nothnagel made on animals several years ago, in Jena, acts upon the vagus, as well upon its centre in the medulla as upon the peripheral ends in the heart-muscle itself. It slows and strengthens the heart's action, and increases the arterial tension. In too large or too long continued dose exactly the opposite effect is obtained. Digitalis belongs to the cumulative poisons, hence caution is required in using it for any length of time. It owes its properties to four alkaloids, no one of which alone, and no combination of them, except as found in the plant, will replace it.

Digitalis is only to be given when the heart-muscle becomes weakened and flags. It is the greatest mistake to give the drug, simply because there is a lesion of the valves, without disturbance in the circulation; also, it is to be given in *all* cases of circulatory disturbance due to lessened action of the heart-muscle, whether the original cause of the trouble was an affection of the valves or sclerosis of the arteries, contracted kidney, chronic bronchitis, emphysema, etc.

The English say that a certain valve-failure, insufficience of the aorta, contra-indicates digitalis. Nothnagel believes that this is a mistake; he has always seen good results from its use in this as in the others. As to the preparations, he prefers the powder or the infusion. The powder he has found to be the best working form. In valvular disease always begin with small doses, frequently repeated; three grammes (.03) of the powder every three hours, continued for five or six days, then stop the medicine entirely for five or six days, and repeat as before. If necessary, five grammes (.05) every two hours may be given. If this is not enough the condition is very bad. Professor Nothnagel has given as high as ten grammes at a dose in extreme cases If, with a dose of five grammes, the desired result is not obtained, it is best not to give any more; the case is very bad and the prognosis fatal. It is best in this case to try the few other remedies that are available. During the administration of digitalis the physician must observe the patient closely and continually; the poisonous symptoms come on very suddenly, the first symptoms are very frequent, pulse with small tension and vomiting.

When given properly digitalis is a powerful and exceedingly valuable remedy. A combination of quinine with digitalis is sometimes of service, from three to fifteen grammes per day. Scylla, which is recommended by some authors, will not replace digitalis, as it only works in exactly the same cases where digitalis does, and only feebly and when given in very large doses. Adonis vernalis has been tried very thoroughly in this clinic, with negative results. It can be tried, but must be given in large doses, three to seven grammes of the powder per diem. Convallaria the professor thinks of little value. Caffein, in doses of one to three grammes of the simple salt, is a very good complimentary means. It is more of a diuretic than a heart-stimulant. It may be used where digitalis fails entirely, and has been found in some cases to be of value.

Professor Nothnagel usually begins treatment with digitalis, or more rarely with digitalis and quinine, if no result is obtained from this he uses caffein.

The first occurrence of the rupture of the compensation is usually immediately relieved by digitalis, and apparently, excepting that valve lesions still remain, the patient entirely recovers. The hydrops and œdema of the organs, and secondarily the emphysema of the lungs, has been driven away; has been removed by the digitalis. But a second attack occurs, which is more slowly relieved, and a third attack, and the patient ultimately dies, water-logged, of the original disease.

In a following lecture, Professor Nothnagel, after describing several of the older remedies and methods used in treating acute articular rheumatism, and condemning most of them, said that the simplest, most certain, and satisfactory therapeutics for this disease was salicylate of soda. He laid particular emphasis on the statement that the disease was a general disease, in which several organs of the body were involved: the heart in its separate structures, the endocardium, the myocardium, and pericardium, the sweat-glands, the joints, and the pleura, bronchi, and meninges, to a greater or less extent. The disease was evidently the result of a general poison, and as quinine was a specific to the poison of malaria, or mercury a specific to the poison of syphilis, so was salicylate of soda a specific to the poison of acute articular rheumatism. This disease is self-limited, however, and by the old methods of treatment, or if left alone, it usually ran its course in four weeks, doing considerable damage or causing death. With proper treatment there should be marked improvement in the joints in twenty-four hours. Salicylic acid has a similar action, but can not always be given, because of its effect on the stomach. When the pain in the joints and the fever is very severe, Nothnagel gives sodii salicylate in one gramme doses every hour, when less intense he gives twelve to sixteen grammes every twenty-four hours. In giving this drug, watch

must be kept upon the heart and stomach. It produces also, in many cases, a roseola. After the acute inflammatory condition disappears, which is commonly in from twenty-four to fourty-eight hours, the medicine is kept up in much smaller doses, from four to six grammes per diem for two or three weeks. This remedy does not stop the endocarditis, but it renders it much less severe, and this process disappears more quickly. In some cases, as quinine in malaria, sodii salicylate fails; in these cases it is found that benzoate of sodii is of great service. It must be given in doses of considerable size, sometimes as high as thirty to forty grammes a day. Vesication may be used about the joint, never on it, and iodide may be tried after failure of the above means.

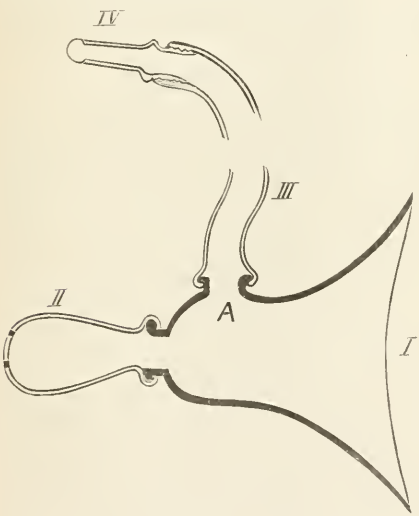
New Instruments.

NIPPLE-SHIELD.

By CHARLES WARE, M.D.,

NEW YORK.

The accompanying nipple-shield was first used by me in a case of depressed nipples which came under my care about a year ago. It gave such good satisfaction in that case, and the mother seemed so much pleased with the way it worked, that I applied to my friend, Dr. F. H. Markoe, to have one tried at the Nursery and Child's Hospital. The nipple-shield which I sent there last May has been in almost constant use since that time; and I learn from the House Physician, Dr. I. H. Hance, that it has done more than was expected of it.



As shown in the drawing, I have taken the ordinary No. 2 shield and opened it at A for the attachment of a rubber tube six to eight inches long, with a hard-rubber (iv.) mouth-piece at the end. After the shield is applied to the breast, the rubber tube is carried to the mother's mouth. By compressing with her fingers the nipple (ii.) the mother can exhaust the air from the nipple-shield and fill it with milk before the child is put to the breast. When the child begins to nurse, the mother must close the tube leading to the mouth, either by bending the tube or by placing her thumb on the opening at A. The child is thus less likely to bite the nipple, and is saved the annoyance of sucking air and of pulling at the nipple-shield for some time before being rewarded for its efforts. The new nipple-shield has already been tried in a great many cases, and I feel warranted in suggesting its use in cases of depressed or sore nipples when any nipple-shield is indicated.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 8, 1885, to March 14, 1885.

Brown, H. E., Major and Surgeon. Granted leave of absence for one month, with permission to apply for two months' extension. S. O. 48, Department of the East, March 6, 1885.

Taylor, Blair D., Captain and Assistant Surgeon. Leave of absence extended two months. S. O. 54, A. G. O., March 9, 1885.

Brown, Joseph B., Lieutenant-Colonel and Surgeon. Detailed for Army Medical Board, to meet in New York City, April 6, 1885. S. O. 56, A. G. O., March 11, 1885.

Heger, Anthony, Major and Surgeon. To be relieved from duty in the Department of the East and detailed to Army Medical Board, to meet in New York City, April 6, 1885. S. O. 56, A. G. O., March 11, 1885.

Janeway, John H., Major and Surgeon. To perform duties on the Army Medical Board in New York City, April 6, 1885, in addition to his present duties. S. O. 56, A. G. O., March 11, 1885.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 14, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
March 7, 1885	0	6	95	1	174	47	0	0
March 14, 1885	0	5	84	9	177	73	0	0
Deaths.								
March 7, 1885	0	2	12	0	25	23	0	0
March 14, 1885	0	1	21	8	25	39	0	0

The Removal of the Cæcum for epithelioma is the subject of a report by Mr. W. Whitehead, of Manchester, Eng.; it is reported in the *British Medical Journal* of January 24, 1885. The patient died, however, on the thirteenth day.

The Number of Bacteria per cubic metre in city air is about 2,500; in the air of a city hospital, it is about 11,000 per cubic metre, reaching the minimum in summer.

A New Remedy for Migraine proposed by the French, is a decoction of the leaves of ményanthe, a plant of the family of gentians.

A Case of Obstinate Hiccough Cured by Jaborandi is reported by Dr. Pagenstecker, of San Louis Potosi. One dose producing physiological effects was sufficient.—*Bullet. de Thér.*

That Albuminuria is not a Contra-indication to Ovariotomy is the conclusion reached by Dr. R. W. Wilcox, after a careful study of the subject.—*St. Louis Medical and Surgical Journal.*

REMARKS ON DIPHTHERITIC CROUP, AND THE QUESTION, "IS THE OPERATION OF TRACHEOTOMY IN DIPHTHERITIC CROUP DANGEROUS?"

By ADOLPH RUPP, M.D.,

LATE ATTENDING PHYSICIAN TO THE NORTHERN DISPENSARY; AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

(Continued from page 314.)

IV.

DR. WINTERS, who advocates "early" tracheotomy, says: "But while the symptoms of suffocation and of pneumonic changes may be relieved by the late performance of tracheotomy, they may often be *prevented* by the early introduction of air into the lungs" (THE MEDICAL RECORD, December 13, 1884). He also teaches: "The great reason why bronchial and pulmonary complications follow tracheotomy where it is performed for croup is, that where obstruction has continued a long time the lungs are in a state of congestion, and in this condition any slight irritating cause, such as would act harmlessly on healthy lungs, will hasten on to dangerous inflammation. When it has been decided that a positive mechanical obstruction to the entrance of air into the lungs exists, do not wait until lividity sets in before making a way for easy respiration. Let the operation be done before secondary complications have arisen, or the accession of those symptoms, which are in themselves extremely dangerous to life, which often render all treatment unavailing, and make the removal of the mechanical obstruction of less importance."

About thirty years ago Dr. H. W. Fuller answered arguments like these as follows: "It is asserted by those who advocate an early performance of tracheotomy that much engorgement and inflammatory mischief in the lungs is prevented by admitting a free supply of air at an early stage of the disease, and that the patient being stronger than at a later period, is better able to undergo the fatigue of operation and to cough up false membrane, or the thick tenacious mucus by which the bronchi are obstructed and the breathing is oppressed. But however plausible these suggestions may be, they must not be allowed to influence our practice, unless it can be shown, first, that pulmonary engorgement so commonly presumed to exist during life is not attributable to the irritative influence of the disease; secondly, that if referable to obstructed breathing it occurs as soon as the second stage has commenced; and thirdly, that when suffocation is approaching the patient is unable to bear the operation, or has not sufficient strength to cough up and get rid of accumulations in his air-passages. And experience seems to negative these suppositions. The operation," he goes on to say, "is usually well borne, and expectoration takes place freely and easily as soon as the trachea is opened. In four out of five cases recorded in this communication, in which the operation was not had recourse to until collapse had set in, and death was, so to speak, commencing, none of these theoretical difficulties were observed, nor were they in more than one or two of the cases, whether successful or unsuccessful, of which I can find records in English literature. On the contrary, it is almost invariably remarked that in a space of time varying from a few minutes to half an hour after the operation, the patient coughed up some mucus or false membrane through the artificial opening, appeared much relieved by so doing, and fell asleep, breathing easily, . . . facts quite inconsistent with the existence of any great degree of persistent pulmonary engorgement" ("Med.-Chir. Trans.," vol. xl.).

From the cases above quoted it becomes clear that the statements of Dr. Winters, just quoted, are not clear. We know that the diphtheritic exudative progress may extend in spite of even an early operation. And Dr. Jacobi and others assure us that this process may extend into the larynx from below. Dr. Winters himself has found in his examinations of recorded autopsies that "secondary changes"—"œdema of the lungs and pneumonic changes"—belong to "a smaller number of cases" in non-tracheotomized cases of diphtheritic croup and presumably so in cases "where tracheotomy had been performed in the third stage of croup and death followed soon after." Knowing all this, and what other reputable men have taught and do teach, it becomes difficult to see why a so-called "late" operation may only relieve, while an "early" operation will emphatically *prevent* pneumonic changes.

Dr. Passavant (of Frankfort-on-the-Main) also advocates early operations, but in a manner that does not offend one's modesty. This surgeon even goes so far as to hint at prophylactic tracheotomies for the possibilities of croup and diphtheria that have not yet announced themselves. In the field of tracheotomy Dr. Passavant has done good work. He speaks from a thirty years' experience. He does not think that the pulmonary condition found before and after death warrants a prophylactic operation in diphtheritic croup, but he does think an early tracheotomy is called for. He does not claim that an early operation is without danger, but he holds that the advantages offered by an early operation outweigh the attendant possible dangers. An early operation may encounter less swelling and engorgement of the veins of the neck, an advantage to the patient and surgeon, and thus an early operation may be less bungling than a late one. The advantages of an early operation may be formulated thus (Passavant):

Firstly.—It prevents or lessens the chances of death by suffocation.

Secondly.—It facilitates the expectoration of mucous and pseudo-membrane.

Thirdly.—It allows time for the disease to exhaust itself.

Fourthly.—It facilitates local treatment.

Fifthly.—It in a measure spares the strength of the child.

Sixthly.—It adds to the chances of due pulmonary circulation.

Seventhly.—Possibly the progress of the diphtheritic exudation is prevented.

Dr. Ripley, as a rule, does not favor early operations, because *not unfrequently* they are unnecessary—because tracheotomy in diphtheritic croup is in itself dangerous, and may secondarily jeopardize life by erysipelas, abscess, etc., and finally because of the permanent injury that may result to the larynx and trachea.

Passavant says of the operation, though as a rule not dangerous when due care is exercised, and though it often turns out to have been easily consummated, it is not, in his opinion, an easy one, as has been asserted by some. Every operator, he says, who has operated often,

will have had cases which gave him cause to fear that the child would die under his hands.

We know now *why* some would operate "early," *why* some would operate "late;" but it is not so easy always to determine what is meant by an "early" or by a "late" operation.

One writer, a proclaimed early operator, tells us that "it is the duty of the attendant to operate early in the first indication of abiding stenosis," and that "it must be left to the attendant to decide whether the stenosis is abiding or paroxysmal." He says nothing as to the degree or amount of abiding laryngeal stenosis, but he is bold to say that it is criminal to wait until cyanosis hangs out the danger signal. All this is vague. I am sure a certain amount of laryngeal stenosis may exist, and still an operation will not be called for. As to cyanosis in diphtheria, that is a matter to be considered, and may be due to causes other than laryngeal stenosis, and even when laryngeal stenosis also complicates, these other causes may be at work too. It is not a wise thing to do to judge others harshly by anticipation, and more especially so in cases where it is not only admitted but affirmed that the attending physician must judge as to the case and all concerning it. This same writer instances the following interesting experience. He says he has himself "watched a case of laryngeal stenosis an entire night, while instruments and table were in readiness for tracheotomy, which was found unnecessary when the morning dawned."[1] I wonder how many times during this night did Dr. Baruch convict himself of criminality? Another advocate of early tracheotomy in diphtheritic croup teaches: "When there is suppression of voice, and *expiration is labored* [italics mine], *prolonged, and audible*, there is no longer doubt about the presence of membrane" in the larynx; and immediately this state of affairs has become established we ought to tracheotomize, for now there will be "no longer remissions between the croupal paroxysms, but the dyspnœa continuous;" nor are these the only indications marked by Dr. Winters for our guidance in doing early tracheotomies, for he continues: "If insufflations of alum and sulphur, with ipecacuanha, cease to afford relief, or emesis can no longer be produced, and ipecacuanha only purges, and poultices and steam have been fairly tried, it may be said that all remedial measures have failed to control the disease, and the operation should at once be performed."

I should say so! But if we allowed ourselves to be guided by these indications in all cases we would not in all cases needing operation tracheotomize early enough. Recession of the soft parts of the chest-walls Dr. Winters looks upon as "a valuable test of the amount of interference with that act," but he holds it to be a not reliable guide "if the expiration is free and easy, for these symptoms may be due in great part to spasm."

Long ago Porter[2] said: "There is something exceedingly acute about the sensibility of the larynx, it soon feels the presence of even a slight impediment, and its action and efforts are redoubled to preserve respiration. Thus its muscles are thrown into violent and often irregular actions, there is spasm and cough, and the windpipe is moved rapidly and violently upward and downward in the neck; the patient then becomes anxious and agitated under the horror of suffocation, and all the muscles of inspiration are made to assist in expanding the chest and filling the lungs with air. Yet these symptoms may be produced while the larynx is only partially diminished in size, for I have seen a patient breathe through a tube the calibre of which did not approach near the dimensions of the rima glottidis."

All organs having active functions are possessed of what may be termed a reserve of functional power or capacity, and the lungs are not exceptional in this respect. That is, the lungs possess compensatory powers, and the same may be said of systemic respiration. Cases like that of Barker's demonstrate this. I have seen children breathe through a very much obstructed glottis, and live quite comfortably. We may say, given sufficient time the lungs and the system generally habituate themselves to a less volume of tidal and residual air. And the same may be said of the compensatory power of the circulation. That is to say, when obstructed respiration has become balanced, the circulation becomes so too, and the newly imposed conditions—the laryngeal condition ceases to offend, or in great measure so. This being true of chronic abiding laryngeal obstruction or stenosis, it may also be held to be so for the more or less acute stenosis of diphtheritic croup, but, of course, to a much less extent than is the case with chronic abiding stenosis. I treated a man for true non-diphtheritic croup, in whom the diagnosis had been made laryngoscopically as well as by other means, several years ago. Here the false membrane was thick and hard, and remained several days longer on one side of the larynx[1] than on the other. There was a good deal of œdema of the ary-epiglottic folds and of the false vocal cords. When I was first called to this man he was in a most distressing condition. He was livid, could not lie down, and covered with cold sweat. His eyes were protruded and had a wild stare. The lower portion of his chest seemed contracted, and his attempts at inspiration though intense, seemed fruitless. He was voiceless; but he would not be tracheotomized. After about ten minutes the intense orthopnœa gave place to a comparatively bearable amount of dyspnœa. I attributed this relief in great measure to chloroform which I had administered unstintedly. I had used about four ounces within about ten minutes. The œdema of the larynx and the false membrane continued, and within the next three days he had several attacks of severe dyspnœa, which chloroform relieved. The œdema, and the false membrane very much less so, diminished the calibre of the glottis; but the man could breathe comfortably when quiet. The difficulty was more with inspiration than expiration.

I have already said the presence of a foreign body in the larynx is a question of kind as well as degree, in so far as either in- or expiration is concerned, or both at the same time. Bryant's case of foreign body in the larynx shows this much, that there was greater obstruction to the incoming than the outgoing current of air. How else could the *airless* condition of the lungs have occurred? Grown-up people bear membranous formations in the larynx better than small children do, and paroxysmal dyspnœa is more apt to occur in children than in older people. And considering that early operations are advocated, when membranes are forming in the larynx, or œdema of an inflammatory type, and that the younger the child usually the less tolerant is its larynx, the smaller the glottis lumen, and the greater the predisposition to suffocative paroxysms, etc., are probably the reasons why Passavant would call a tracheotomy in diphtheritic croup justifiable if performed after the first paroxysm of dyspnœa. He would operate when respiration ceases to supply the needed quantity of oxygen, and duly carry off the generated carbonic acid, etc. He also states that the operation should not be deferred until grave pulmo-circulatory disturbance has become established, but I do not recollect that he teaches us to recognize it before it has become established. Dr. Passavant, and so, too, Dr. Winters and Dr. Baruch, as well as so-called late operators, are all intent on doing the best that can be done for these unfortunate diphtheritic croup patients. All of us watch and work with this end in view. Passavant justly says: "In determining the time for operating, not only the danger of suffocation demands due consideration, but also the damage sustained by the pulmonary circulation in consequence of the dyspnœa." Difficult inspiration is harmful to the circulation, and so is difficult expiration, and more

[1] The Medical Record, December 20, 1884. Baruch to Editor.
[2] Observations on the Surgical Pathology of the Larynx, etc., p. 46.

[1] In the larynx above the false vocal cords the epiglottis was free, but red and œdematous.

harmful than either alone is impeded in- and expiration.

How long can "free and easy expiration" be carried on when with each inspiration there is retrocession of the soft parts? That is a difficulty that Dr. Winters did not make definitely and unmistakably clear.

Professor Friedrich thought tracheotomy in diphtheritic croup indicated when the patient could no longer expectorate mucus and false membrane because of weakness; when the signs of asphyxia began to show themselves, cyanosis and sopor; when the patient continued getting worse in spite of other remedies, in conjunction with the stridulous piping breathing, dyspnœa, and suffocative paroxysms.[1]

Professor Schüller, following Hueter, would tracheotomize when the infrasternal region sinks markedly with every inspiration in connection with the oncoming of labial cyanosis. He draws attention to what most of us must have noticed, that much stridulous breathing and little dyspnœa may be associated, and a good deal of dyspnœa with very little stridor.[2] A country practitioner, to whom I had put the question, whether in his fatal cases of diphtheritic croup he had observed difficulty of *expiration* or *inspiration* oftenest, was at first a little puzzled, and then answered the difficulty had been with both inspiration and expiration. This physician had done tracheotomy in such cases, and said he had been guided by the general condition of the patient, and the influence that the impeded respiration had on the general circulation. He believed that the profession generally would side with him as to the correctness of his views. I think so, too.

R. W. Parker says: "It is not easy to specify the exact moment that an operation ought to be done. If the dyspnœa is very intense—other remedies having failed—there is no choice but to operate."[3] Nearly five years ago Dr. Ripley, in a very good essay on diphtheritic croup, said: "But, after all, I have been able to find but a single pathognomonic symptom of true croup, *continuous and progressive laryngeal stenosis.*"[4] And, speaking of the use of emetics in the treatment of laryngeal stenosis in diphtheria, he said, "Of these I consider either the sulphate of copper or the yellow sulphate of mercury as the most prompt and sure. But I cannot too strongly deprecate the custom of repeatedly exhibiting these depressing and exhausting agents in the vain hope that they may ultimately succeed. They only jeopardize the last chance to be given the patient by the operation of tracheotomy."[5]

However, as a rule, Dr. Ripley is not in favor of early operations. He would have all cases of diphtheritic croup closely watched; and he does not deny that cases occur which justify, perhaps demand, an early operation. He teaches, ordinarily we ought to wait until respiration becomes continuously labored, with marked symptoms of cyanosis, and beginning failure of the vital powers.[6]

The choice of time for tracheotomizing is not always left with us. We very often must operate when we may. And when laryngeal stenosis is the great cause of the dyspnœa and progressive cyanosis, no other complication should influence us against urging the necessity of tracheotomy. Not pneumonia; not an accompanying exanthem; not albumen in the urine; not even a state of almost lifelessness and all but completed death, if parents can be persuaded, should be allowed to withhold from the patient a chance for life. The operation promotes euthanasia, but should be undertaken for the more serious purpose of saving the life of a patient threatened by death from asphyxia due to the complication of grave laryngeal stenosis.

Excepting the prevention of the progress of the diphtheritic exudation, all the advantages claimed by Passavant for "early" operations may be claimed for "late" operations. And it is clear that early operations do not prevent the advance of the diphtheritic exudation. Passavant teaches that no pulmonary change induced by diphtheritic croup warrants a "too early" prophylactic operation.

J. Solis Cohen speaks of "timely" operations. I do not believe that men who have learned to practically appreciate the value of tracheotomy as a life-saving operation in diphtheritic croup would advocate operations that might be called "too late." We have seen that Dr. Winters advocates "early" operation, yet speaks of ipecac until it ceases to produce emesis but purgation; and that Dr. Ripley cautions against the persistent use of emetics, but does not as a rule advise "early," but a "late" operation; and by no means one that would be too late.

The system, as an organism, has more or less talent for adapting itself to abnormal conditions; to a certain extent, even for conditions suddenly imposed. Respiration, as a function, to a greater or less extent, adapts itself to "abiding" laryngeal stenosis, but if this stenosis "progresses," the respiratory adaptability soon ceases, and the peculiar symptoms with which we are all familiar manifest themselves.

"Early" and "late," as terms giving significance to the operation of tracheotomy in croup, are rather indefinite unless accompanied by those clinical signs believed to tell the arrival of the moment for an "early" or for a "late" operation. Cohen's term is the preferable one; the operation ought to be timely. This the attending physician must settle. But no child should be allowed to die from the effects of a persistent progressive laryngeal stenosis, incidental to diphtheritic croup, if the physician can help it.

V.

"The most important of all questions, the danger of the operation itself." So says Dr. Winters, and he goes on to say, "The quotations from so many eminent authorities of vast experience in the performance of tracheotomy prove beyond all peradventure that the opinion that it is a dangerous operation is erroneous, and it is not only erroneous but dangerous." The quotation of the *opinions* of authorities of vast or of little experience is not sufficient to settle this question. J. Cheyne was an able physician in his day, and he was of the opinion that the operation of tracheotomy was a formidable one. Dessault, a reputable surgeon in his time, had a very sad experience while performing tracheotomy in a child, his first incision bringing on hemorrhage, causing the death of the patient. He called tracheotomy an ever grievous wound. Passavant's opinion of the operation we are already acquainted with, and I shall quote him again. Passavant says, "The prevention of hemorrhage is the point which has been attended to specially in recent times, and it is owing to efforts in this direction that the operation is done with greater safety and more despatch than used to be the case."

Mr. Pye, in his recent work on "Surgical Handicraft," styles tracheotomy a serious operation. In the preliminary discourse to Robert Boyle's collected works, may be read the following words, which will be appreciated by every medical student: "When an author acquaints me only with his own thoughts and conjectures, if he mistakes in his reasoning I am in some danger of erring with him; at least I may lose all the time and pains I bestow upon him; but if a writer endeavors, by enriching his discourse with new and real observations or experiments, to credit his doctrine, let his private opinion be ever so erroneous, yet his experiments being true, I may make my own use of them, and even plead them against his opinion; so that such a writer will certainly teach me useful truths, and cannot easily lead me into error."

I find that Dr. Winters is rather rhetorical than matter-of-

[6] Ibid., April 5, 1884.

fact in the advocacy of his "proper conception" of tracheotomy. He has not only not duly noticed the dangers and difficulties which most ingenious and practised surgeons have met with while doing tracheotomy; he has not enriched his essay "with new and real observations or experiments;" nor has he given proofs to show that tracheotomy is harmless, as he avers it is, and that by misrepresentations of its true character "its abandonment has several times in history" been caused. He says "there is a universal impression that the operation is extremely dangerous to life," whereas, according to his conception, it is only the mere making of a hole into the windpipe. For such statements as these, and for others similar to them, nothing is offered except their statement as a warranty of the truth of them. I do not intend to offer instances of every danger and difficulty that may be encountered in the course of a tracheotomy, nor shall I offer instances of very exceptional occurrence.

Dr. Ripley, who has been represented as being extreme in his expressions regarding the dangerousness of tracheotomy, has himself recorded a number of such operations which presented no difficulties from beginning to end, and little hemorrhage besides. Dr. Ripley has his reasons for holding that it is a dangerous operation, and he having published them,[1] I need not repeat them here. For a full discussion of the difficulties and dangers that the operation may and does offer, I refer the reader to Professor Gross' work on "Foreign Bodies in the Air-Passages," especially to sections ix. and x., pp. 257 to 281. Gross did not believe tracheotomy to be an easy operation, though he himself had been told that "tracheotomy is the most simple thing in the world."

For a description of the technique of the operation the reader is referred to the text-books. My object is to show that the operation cannot fairly be looked upon as either easy or harmless.

Fergusson[2] said: "Laryngotomy and tracheotomy may be performed on the dead subject, and thus some idea may be formed of these operations on the living body." An idea is no doubt formed, but as far as doing it in the living body is concerned, only a very inadequate idea can thus be formed. Describing the operation he says: "It may happen that these proceedings, when required on the living body, will be accomplished with as little trouble almost as on the dead. But it will often be otherwise, and many circumstances may be connected with them which will call forth much of the skill and coolness of the operator." Fergusson further says: "In some instances it would be highly improper to wait until all hemorrhage had ceased before penetrating the trachea;" and he continues: "Without wishing to detract from the danger of bleeding, I nevertheless doubt if any one ever died from internal hemorrhage on these occasions. I have myself seen blood flow freely into the trachea from such wounds, but it has been speedily and as freely ejected again, and, for my own part, the bleeding which I should most dread would be from a copious flow externally."[3]

Sir Benjamin Brodie says in this connection: "If you open the trachea when bleeding is going on, the patient may be suffocated by the surgeon opening the trachea too hastily, and allowing it to become filled with blood. I know a case in which a surgeon performed tracheotomy and the patient died almost directly. On examining the body, as I am informed, the trachea and bronchi were full of blood."[4]

On this point Erichsen writes judiciously as follows: "Many surgeons of authority in these matters advise that the windpipe should not be opened until all, or nearly all, the bleeding has ceased. . . . But in this way valuable time may be consumed and the patient may be fatally exhausted by a tedious and prolonged operation, and by the loss of an unnecessarily large quantity of blood. . . . Hence, except in those instances in which an arterial twig, or large venous trunk, has been wounded, and which must, of course, be secured, the occurrence of bleeding, though tolerably smart, need not deter the surgeon from opening the windpipe, as the relief afforded to respiration will induce a corresponding and rapid diminution in the venous turgescence of the neck, and in the consequent flow of blood from the wound."[1]

Billroth, Roser, and others were not in love with tracheotomy, in so far as their experience with the operation is concerned in Switzerland. Necks in that country are frequently short and vascular, and the thyroid glands excessively developed. These facts explain the opinions of Billroth and Roser as to the formidable character of tracheotomy. Roser, it is said, preferred a difficult jaw resection to doing tracheotomy. This extravagant hemorrhage, peculiar to Billroth's Zürich tracheotomies, is very rarely, if ever, encountered in this country. But a surgeon may meet with severe hemorrhage even in this country in the performance of tracheotomy. Our population is mixed, Swiss live among us, others besides Swiss have large thyroid glands, and large and full veins over the trachea, and asphyxia aggravates peculiarities of this kind.

Hamilton[2] tells us that "veins lie close upon the trachea, and I have myself in one case had a profuse hemorrhage, caused by the accidental section of one of them at the very moment that I was cutting the rings of the trachea." Would it be fair to say that this accident was due to carelessness on the part of Professor Hamilton? I think not. Professor Hamilton teaches that to avoid wounding the veins and arteries use should be made of blunt instruments.

Mackenzie says the use of an anæsthetic increases the danger of the operation, "for if any blood passes down the trachea the chance of suffocation is much greater when the patient is unconscious. I have myself seen two cases in which this accident occurred under chloroform with a fatal result."[3]

Heath in his "Minor Surgery" describes tracheotomy, and says (p. 103): "This is frequently one of the most trying operations the house-surgeon will be called upon to perform." He also states that "it would take much more blood than is ordinarily shed to choke the lungs as has been suggested." This may be an encouraging way of stating a possible accident, but it is not an exact way. This kind of choking has not been suggested, but demonstrated. And this accident has occurred in the best of hands. Fuller, in his essay already quoted from, relates the following case: A girl, sixteen years of age, had been treated for croup by Dr. Bence Jones. She was tracheotomized by Mr. Howett. At the time of operation the pulse was imperceptible, the lips were no longer blue but pale, and she was bedewed with a cold perspiration. Soon after the opening had been made into the trachea she coughed up a considerable quantity of blood that had trickled into the trachea, and almost instantly expired. After death the trachea was found to contain about ʒ ij of blood, partly fluid.

The following case, from the same source as the above one, is very instructive, and illustrates an additional danger. A boy, aged five years, under the care of Dr. Naime for diphtheritic croup, was tracheotomized by Mr. Pollock. "As soon as the trachea was opened the child became more tranquil, and appeared to breathe without much difficulty. Soon afterward he fell into a doze. The breathing continued tranquil throughout the day; the pulse improved; the countenance assumed its natural color; and the cough, which recurred at intervals, led to the ejection of a considerable quantity of shreddy mucus and false membrane through the tube. He passed a tolerably tranquil night, and next morning was much

more comfortable; but in the afternoon the tube became obstructed, and great dyspnœa ensued. With a view to the introduction of a new tube, it was thought necessary to enlarge the opening into the trachea, and during this operation a good deal of blood escaped, some of which trickled down into the air-passages and caused excessive dyspnœa, which never ceased until the child died suffocated shortly afterward."

Post-mortem examination revealed "the lining membrane of the trachea covered with a thin layer of albuminous deposit mixed with stringy, tenacious mucus and blood; and the membrane was tinged of a red color. The larger bronchi presented a similar appearance, but to a much less extent. The lungs were congested, and the smaller bronchi contained a good deal of thick mucus mixed with blood."[1] And Fuller comments on this case thus: "There was nothing in the condition of the parts at the time of the operation to preclude the chance of recovery."

Concerning the sources of hemorrhage Porter, in his book, says, "Some of these are irregular vascular distributions, seldom to be met with, and others, however constantly present, may always be avoided by an operator who is aware of their existence" (p. 259), and "the veins, the large ones, may easily be drawn aside by a curved probe or director, and may in every instance be avoided if the operator proceeds with caution." This is mainly opinion, and though often true, certainly is not always the case. His Case XII. bears me out in my criticism. This case was operated on because medicine held out but little hope—and without expectation of success. "At the first incision some superficial veins were wounded, which poured out blood in fearful abundance. The child could not cry but it struggled violently, and these struggles increased the hemorrhage to an apparently alarming extent. The operation was continued with considerable difficulty, the parts being obscured by the blood—eventually the trachea was opened—bloody mucus was expelled by the wound with force, respiration became easy, and the boy fell asleep half an hour later. Mucus accumulated in the trachea, which aspirating with a syringe failed to remove. The child became weaker every minute, stupid, almost comatose, and died twelve hours after the operation. A branch of the thyroid vein had been slit up its entire length, and the connecting slip between the lobes of the thyroid gland had been divided."

I think from the foregoing, we may conclude that tracheotomy even in the hands of the most experienced surgeons, presents dangers of no insignificant character, and extremely mortifying results, may take place. For these results the surgeons are certainly not to blame. I have not presented all the known, all the published facts, which go to prove that tracheotomy may turn out to be, even in localities outside of Switzerland, a most distressing if not very dangerous operation, in so far as hemorrhage is concerned. Accidents such as we have passed in review have occurred in an unforeseen way. They may occur again, however hard we may try to get rid of any "misconceptions" concerning the operation, however willingly one might choose to believe it ought to be bloodless; but in spite of all so-called proper conceptions of what an operation ought to be, tracheotomy will remain objective in all its usual and other possible eventualities. "Proper operative conceptions" evolved out of the "inner consciousness" may affect practitioners with a delirium of delight, from which they may be awakened to sober views only by some real sad experience. Experience, as we have seen, does not give support to much that Dr. Winters has asserted regarding hemorrhage to be met with in performing tracheotomy. Indeed, his "proper conception" becomes absurd.

The difficulties and dangers of tracheotomy go together very much. The use of blunt instruments is not without danger, for too great violence in their use, says Mackenzie, may give rise to cervical cellulitis.

[1] Medico-Chirurg. Trans., vol. xl., pp. 44, 45.

Dr. F. H. Hamilton says, "The depth at which the trachea lies below the surface of the integument is seldom less than an inch, generally it is much deeper, and I have operated once when it was full two inches and a half."[1]

At Langenbeck's clinic it was found impossible to do inferior tracheotomy three times: once because of the very wide isthmus of the thyroid gland; at another time because of an enormous convolution of intensely engorged veins; and then again because of "a very short and fat neck" of a girl three years old. In these cases superior tracheotomy was done.

Of course instances of this kind are rare, but sufficiently often to nullify any sweeping statement.

Placing the canula into the trachea is not always an easy thing to do. If it were, Mr. Mackenzie could not say that he has *often* seen young surgeons fail in doing so. Sometimes, he says, it is due to the tracheal rings not having been sufficiently divided—and sometimes to the canula having been pushed into the tissues in front of the trachea. Others besides Mackenzie have known this error to have been committed. In this connection the following is an interesting case, besides showing the possibility of another grave misfortune; it is Case XI., spoken of by Marsh. The canula had been placed in front of the trachea instead of into it. This false position was not suspected "until a sudden and large hemorrhage from the wound proved fatal. On dissection it was found that the end of the canula had projected against the innominate vein, in the coats of which a small ulcerated opening could be seen."

It may be said that such cases as this can take place only when gross carelessness or stupidity directs an operation. Perhaps such a judgment would be the correct one in such cases. But on the other hand, does not the promiscuous and unconditional recommendation of tracheotomy in diphtheritic croup, as has been done, make itself responsible for mistakes of this kind, at least in a measure? At any rate the difficulties and dangers of this operation are sufficiently grave and numerous, as may be learned from the experience of the best surgeons of all countries, to make it well advised to be sober and temperate in the expression of *opinion* as to its being *simple and easy*, and dangerous only when carelessly done. Sir Arthur Helps puts in a plea for charity toward those who may not be as deft and expert in those things so easy for ourselves. This humane plea is as appropriate in the practical concerns of medicine as it is in all other practical concerns of life. The learned are often impatient when the ignorant appeal to them for light; but never so the cultured, for they have learned, as Goethe has it, that all the learning in the world is still no judgment. Learning, to be of use to those whom it ought to benefit, must be tempered by the good sense which experience and charity make possible.

"Décollement" of the tracheal mucous membrane is an accident that happens rarely, but it happened to Professor Pitha, and in the experience of other lesser surgeons. The accident consists in the canula being pushed between the tracheal wall and its lining mucous membrane. In cases of diphtheritic croup this accident might happen, and the patient die under the operator's hands, as did Pitha's case;[2] choked, must we say, because the operator was *wilfully* careless? In putting in the canula the false membrane may be pushed before it and thus be imbedded in a cavity formed by the tracheal wall and false membrane. No current of air is established, because no channel for it has been made.

After the operation has been done, and the canula fixed as it should be, accidents of a grave character may present themselves, and jeopardize the life of the patient, all of which are more or less consequent to tracheotomy. Such are the dangers arising from changing the canula, as witness Pollock's case; cervical cellulitis, abscesses, necrosis of the cartilage, emphysema of the neck, etc., the formation of granulations about the

[1] Op. cit., p. 675. [2] Schuller: Die Laryngotomie, etc., p. 65.

wound and extending into the trachea, ulcerations, tracheal fistulæ, erysipelas, diphtheria of the wound, and secondary hemorrhages.

Of 210 tracheotomies, Krönlein[1] states 50 were affected by diphtheria of the wound, ranging from a mild to a most virulent type, spreading about and deep into the tissues, simulating a gangrenous process. In one of the cases secondary hemorrhage resulted in consequence of the secondary diphtheritic ulcerative process, causing the patient's death.

Zimmerlin reports from Professor Hagenbach's Clinic, that of 141 tracheotomies, 20 were complicated by secondary hemorrhage, and 5 died in consequence thereof. Secondary hemorrhage was rarely observed before the second day.[2]

On this accident of secondary hemorrhage, Marsh writes:[3]

"Hemorrhage occurring some days after tracheotomy is an accident of which very little mention is made in books. This may be because the descriptions written of tracheotomy generally end with the operation itself, while the after-course of cases is very slightly touched upon; or perhaps the accident is very rare, and it may be only by a coincidence that I have met with examples of it. However this may be, it occurred in two of the thirteen cases where I have operated; and without making by any means wide inquiries, I have heard of three besides. The bleeding may be derived from one of the large trunks of the neck, whose coats ulcerate and give way under the pressure of the canula which has come in contact with them (Cases IX. and X.); or it may come, as it probably did in Case VIII., from the surface of the wound; or it may proceed from some of the vessels of the mucous membrane of the trachea."

Case VIII. illustrates this difficulty and danger in cases of this kind so well, even when help is near, that I copy it here: "B. F——, aged five and a half years, was admitted into the Children's Hospital with diphtheria, with which he had been ill eleven days. The disease, at first seated wholly in the fauces, had in the last two days reached the larynx, and produced such urgent dyspnœa that tracheotomy was performed as soon as he was brought into the ward. He did well after the operation, except that there was very profuse muco purulent discharge from the wound, and on the fourth day, as he breathed freely through his larynx, the tube was removed. Six hours afterward, as he was sitting up in bed, about three ounces of blood were poured from the wound, and he fell back and fainted. Before I reached him, although I was in a ward on the next story, hemorrhage had ceased. He was very much exhausted, but he soon rallied, and for a day or two it seemed not hopeless that he might still do well, but he flagged again; albumen, already present in the urine in small quantity, now became much more copious; he wasted quickly, and two days later he died. At the post-mortem the edges of the wound into the trachea were slightly ulcerated. About one-fourth of an inch below the lower extremity of the cut, and on the inner surface of the trachea, were two ulcers, each about half an inch in length and a fourth in breadth; they were parallel to each other, and had partly coalesced. The ulcers had quite eaten through the anterior part of the cartilages. There was a good deal of injection of the trachea generally; but immediately below the cut the redness was extreme, and extended into the bronchi. No ulceration or rupture of any vessel about the seat of the wound could be found to account for the hemorrhage before death."

Henoch[4] relates the following case, which is not without interest: "I shall never forget the case of a four-year-old boy, who had been tracheotomized in the city four weeks previous to his being brought into the hospital. The canula had not, according to the father's statement, been removed since its first insertion. The canula, which was apparently of too large a calibre for this case, was removed only with considerable difficulty. Its removal was followed by a mass of bloody pus coming from the trachea and the surrounding cellular tissue. After two hours, orthopnœa, which had developed, obliged the introduction of a smaller canula, which could be removed the next day, altogether." This last case is a sample of careless treatment, but this cannot be said of the one preceding it. Does not the care and ingenuity that has been devoted to the realization of an ideal tracheal canula prove that medical men are anxious to avoid actual as well as possible dangers incidental to the after-treatment of tracheotomized cases? From this and the facts already mentioned, it becomes clear that the statement that tracheotomy adds not one element of danger to the original disease, is without foundation in fact.[1]

VI.

From my experience I have not been led into believing that tracheotomy is universally believed to be an extremely dangerous operation, nor have my readings led me to believe that tracheotomy has been abandoned because it was thought to be a formidable operation. From the experience of surgeons of Billroth's stamp, we know that it is, at certain times and places, formidable. We also know that it may turn out to have been a comparatively simple undertaking, but this no one could foresee. I have tracheotomized once, the patient died thirty-six hours after the operation, and the parents blamed themselves for having allowed me to operate and me for doing so. The child succumbed to the extension of the diphtheritic exudative process, for which the operation is not to be blamed. I felt happy when the operation was over with, and the tube properly inserted. I had used the knife as little as possible, and then on a director. I had been ably assisted by Dr. Stubenbord, of this city; the father of the child offered to assist and we allowed him to do so, but he proved rather an obstacle than a help. The child was scrofulous and had had extensive bronchitis before we operated. I did not then, any more than now, look upon tracheotomy as curative in any other respect than that it is a remedy against laryngeal stenosis of a persistent and continuous character. I think more than two ounces of blood was lost. Chloroform had been used as an anæsthetic, and its use eased the breathing.

The case was afterward well watched by Dr. Stubenbord and myself, and constantly and carefully watched by Mr. Becker, then a medical student, during the following night. The parents could not be depended upon as nurses, and the other tenants of the house were extremely wise and meddlesome. I have seen some of the best surgeons in the world do tracheotomy, but in no instance did I see them undertake the operation in the spirit common to the doing of "things the easiest in the world."

Not long ago I was speaking on this subject with one of our most deft and careful throat surgeons, who had often done tracheotomy, and he assured me that he always felt much relieved when he had the canula properly fixed into the tracheal lumen. All his other answers were as direct as my questions. His opinion is that it is well to look upon the operation as difficult and dangerous, although it will not always prove to have been so. Before operating it is difficult, almost impossible, to know whether or no the operation will be difficult and dangerous, or easy and bloodless.

In a "special"[2] from Buffalo, dated January 22d of this year, "a charge of fatal malpractice" against a well-known physician is narrated. From the description it seems that the physician believed in "early" tracheotomies, and that he had a so-called "proper conception"

[2] Jahrbuch f. Kinderh., Neue folge., B. xix.
[3] St. Barth. Hosp. Reports, vol. iii., pp. 365, 366.
[4] Vorles. ü. Kinderk., p. 646.

[1] My quotations from Passavant are taken from that portion of his essay on Tracheotomy, etc., published in the Deutsche Zeitschrift für Chirurgie, for December 20, 1883.
[2] To the New York Tribune.

of the operation, for it seems that after consuming "half an hour before reaching the windpipe" he drew the windpipe up with a hook, "so that he could reach it with a pair of shears" . . . "one sharp cut and the blood spurted out upon the carpet" . . . and soon after the child, a seven-year-old boy, died.

I quote this case, not for the purpose of criticising the physician who has been charged with malpractice in this case of membranous croup (that cannot be done, because all the facts of the case are not given by the *Tribune* special), I quote it to show to what the operation may lead; a consequence of no small importance to any practitioner. My sympathies are with the doctor.[1]

Popular opinion is generally against tracheotomy, but not universally so. Many physicians are sceptical as to the benefits to be derived from it;[1] some physicians are apparently over-hopeful as to what it can do. But all or nearly all physicians acknowledge that we must be settled as to *why* we ought to do the operation, and that this is of more importance than making "the hole" into the trachea. We have seen that the "older writers," who it is said always expressed themselves in definite and unmistakable terms, made a study of the indications of tracheotomy; and that it took *hundreds and hundreds of years* for the operation to attain its present state of perfection. We also know that medical men, the most eminent in ancient and modern days, have argued against its utility in certain affections; not because they were ignorant of the operation, not because they lacked the courage of philanthropists; but because it seemed to them to be, when performed in certain instances, a not insignificant evil added to other evils which it could not relieve. These men, it seems to me—and they were such as Aretæus and Cheyne—I say it with diffidence and yet with pleasure, had the true conception of an ideal physician, whose object is to lessen suffering and not to increase it, and to be cruel only to be kind, when cruel he *appears* to be.

Men, it has been said, are but the children of the age they live in. Children are of all sizes and dispositions; precocious and backward, but always children. And it seems to me, from my readings, that the misconception regarding the utility of tracheotomy has been due rather to misconception of the troubles for the relief of which it had been and is proposed, than any misconception as to the danger and difficulties of this operation.

Conclusions: 1. "Tracheotomy of itself, performed with care, involves little if any danger to life" in many cases, but has turned out, in the best of hands, to be immediately dangerous to the patient's life.

2. Accidents during operation, even when care is exercised, may occur, and to say that these accidents are generally due to want of care is to not only overstate circumstances, but to misstate them.

3. It prevents asphyxia when threatened asphyxia is due to laryngeal stenosis, and if the diphtheritic exudative process halts, and does not implicate the bronchi, etc.

4. It prevents laborious and rapid breathing and lessens exhaustion to the extent that these symptoms had been caused by the laryngeal stenosis, now relieved by the tracheotomy, but no more than this.

5. It is the supreme resource for relieving the suffocation due to laryngeal stenosis, but in other respects does not influence the disease. It is not wise to give the operation too much credit, for, if we do so, it may suck us into quarters for which we have no liking.

6. When the operation has been found to relieve the laryngeal stenosis it has answered all it is capable of doing. Of course, persistence of the original disease, *too* long delay in its performance and neglect after, may render the operation futile, but are not to be looked upon as *the* causes of the failure of the operation.

7. The operation should be done in time, *if possible*, that is, when the laryngeal stenosis has become *abiding* and *progressive* and interferes with the due function of respiration. It should not be done unnecessarily early, nor too late, but it may never be too late to operate, for cases in an insensible and asphyxiated state have been brought back to life by the operation.

8. Operate knowingly and with care, and not unnecessarily hurriedly, so that when unavoidable dangers do present they may be properly overcome, and no blame be cast upon you, or your conscientiousness and ability questioned.

9. Statistics prove nothing unless the character of the epidemic is taken into account, and many other peculiarities. Statistics taken collectively show that about one patient in four or five of those complicated by laryngeal stenosis in the course of diphtheria is probably saved from death. All death is "certain" and needs no qualifying epithet.

10. Patients dying after the operation would in all probability have died anyhow, and the best consolation in such an event is that, though life was not saved, suffering to some extent at least was mitigated, and the best known possible good had not been neglected in endeavoring to save the patient's life.

406 West Thirty-fourth Street.

[1] In diphtheritic croup.

A SUMMARY OF TWO HUNDRED AND FIFTY-TWO CASES OF LOBAR PNEUMONIA.

Being the Cases Treated in the New York Hospital from April, 1877, to January, 1885.

Compiled by EDWIN T. DOUBLEDAY, M.D.,

medical clinical registrar to the new york hospital.

The hospital (new building) was opened in 1877; the service was very light, and the system of case-taking not perfected for some months. This will account for the small number of cases recorded in the first two years. During this time some cases were treated of which a complete history has not been preserved. In 1884 eleven hundred and sixty-nine cases of all kinds were admitted on the medical side. Of these fifty-three were cases of pneumonia.

The ages of the patients and the occurrence of the cases will be found to closely agree with the results of other statistics. It is noticeable that a history of infection was not obtained in any of the cases. The death-rate is considerably higher than that given by most observers.

Sex.—Males, 201; females, 51.

Exciting Cause.—No assignable cause in 199 cases; exposure to wet and cold in 47 cases; immersion in 3

cases; prolonged mental labor and loss of sleep in 3 cases.

Alcoholic History.—Some of the patients were undoubtedly alcoholics where that fact is not noted in the history, as the lesions produced by the habitual abuse of alcohol were found on autopsy.

Alcoholic history.	Recovered.	Died.
Not stated	53	47
Absent	21	7
Slight	32	16
Marked	12	27
Very marked	12	25

There was an acknowledged alcoholic history in almost fifty per cent. of all cases, and where the history was marked the death-rate was sixty-eight per cent. The results of the alcoholic habit are one of the prime factors in the mortality of pneumonia.

Chill.—Not stated in 15 cases; absent in 58 cases; present in 179 cases.

Pain.—Not stated in 18 cases; absent in 19 cases; present in 215 cases. In about twenty-five per cent. of the cases, pain came on eighteen to thirty-six hours after the chill. In four cases pain preceded the chill. In seven cases both chill and pain were absent. In the nineteen cases where pain was absent eleven were under thirty-five years of age, and uncomplicated; of these only one died. The remaining eight cases were all over thirty-five years of age and complicated; of these only one recovered.

Crisis.—A distinct and well-marked crisis occurred in 38 cases. Average time of crisis, 8.5 days. Crisis occurred most frequently on the following days: Sixth day, 6 cases; seventh day, 6 cases; eighth day, 6 cases; eleventh day, 5 cases; twelfth day, 5 cases; ninth day, 3 cases. Per cent. in which crisis occurred: Of all cases, 11.1 per cent.; of uncomplicated cases, 27.1 per cent.; of cases complicated with pleurisy, 13.7 per cent.; of cases with other complications, 2.6 per cent. Complications where crisis occurred were as follows: Chronic diffuse nephritis, one case; mitral cardiac disease, one case; empyema, one case.

Temperature.—The temperature of those who recovered was 100° to 104.5°. Few recovered where the temperature ran up over 105°; though one recovered after the temperature had staid at 106.1° for two hours. Ante-mortem rises of temperature generally occurred, commencing one to eighteen hours before death. In ten cases it rose to +106°, in three cases to +107°, in three cases to +108°, and in one case to 110.6°. Depressed temperature occurred in three cases, all alcoholics with chronic diffuse nephritis. They were as follows: Male, aged [illegible] sixty-seven, 98.4°; male, aged sixty-six, 95.6°; male, aged forty, 92.4°.

Duration of Fever.

	Recoveries.	Deaths.
In all cases	12.5 days.	9.2 days.
In uncomplicated cases	10.3 "	7.5 "
In cases complicated with pleurisy	8.6 "	7.3 "

Part Involved.—Right lung: Lower and middle lobes, 28; lower lobe, 24; whole lung, 24; upper lobe, 22; middle and upper lobes, 22; middle lobe, 11; anterior portion of lung, 1; middle lobe and lower two-thirds of lower lobe, 1; whole of lung (except base), 1; middle and upper and part of lower lobe, 1—135 cases.

Left lung: Lower lobe, 38; whole lung, 20; upper lobe, 17; lower lobe and half of upper lobe, 1—76 cases.

Both lungs: Middle and lower lobes of right, lower of left, 10; lower lobes both lungs, 9; whole of right, lower lobe of left, 7; whole of left, lower lobe of right, 2; thirteen other combinations, one each, 13—41.

Of the double pneumonias: All cases, 14, or 33.6 per cent. recovered; 37, or 66.3 per cent. died; uncomplicated cases, 8, or 40 per cent. recovered; 12, or 60 per cent. died; complicated cases, 6, or 28.5 per cent. recovered; 15, or 71.4 per cent. died.

Complications.—Some of these complications (so-called) ante-dated the pneumonia. Pleurisy is only classed as a complication where there was effusion or where the exudation was out of all proportion to the amount of lung involved.

	Recovered.	Died.
Pleurisy	18	11
Chronic diffuse nephritis	4	36
Empyema	5	10
Valvular cardiac disease	6	8
Cirrhosis hepatis	1	8
Syphilis (acute)	4	5
Pericarditis	2	4
Enteritis	4	2
Phthisis	3	3
Parenchymatous nephritis	3	3
Cerebro-spinal meningitis	..	4
Morphine habit	..	3
Acute peritonitis	..	3
Epistaxis	5	..
Delirium tremens	1	2
Lobular pneumonia	..	2
Fatty degeneration of heart	..	2
Herpes labialis	6	1
Delayed resolution	8	1

—and purpura hemorrhagica, pulmonary embolism, abortion (six months), laryngitis, hiccough (six days), gangrene of lung, purulent softening of lung, duodenitis, cerebral softening, chronic cystitis, emphysema, salpingitis, each one case, all fatal; also pregnancy (six and one-half months), molar pregnancy, malarial fever, each one case, abscess three cases, otitis media two cases, all recovered; typhoid and uræmia, two cases each, two recovered and two died.

Treatment.—Aconite has been used in a few cases. Quinine has been used extensively. When given early it was apparently of marked benefit in giving a mild form to the pneumonia and in a very few cases cutting short the disease. When given late, in large doses (gr. xv. to gr. xxx.), for reducing temperature, it has had, in some cases, a marked depressant action on the heart. When the case came in before consolidation had taken place, a dose of calomel (gr. v. to gr. x.) was frequently given. I have seen typical physical signs of the stage of congestion (crepitant râle, etc.) in two cases disappear under this treatment. For the delirium, the bromides, chloral, and morphia, very sparingly, have been used. For pain, opium, generally in the form of liquid Dover's powder. For dyspnœa, small doses of atropia, quebracho, dry cups, and when the consolidation is extensive (double pneumonias), inhalations of oxygen (ciii. to cv. p. r. n.). For stimulants and heart-failure, ammonium carbonate (gr. v. q. 3 h.), fresh tr. digitalis (gtt. v. to gtt. xx. q. 3 h.), and alcohol. Patients are generally put on stimulant treatment as soon as admitted, and the alcohol is rapidly increased as long as the pulse remains poor and the tongue dry, or until the breath becomes alcoholic. Whiskey is the form of alcohol used. The amount of alcohol needed varies much. Some cases required twelve to eighteen ounces in the twenty-four hours. Lately antipyrin has been used for high temperature. It was given in powder gr. xxx.; and, at the end of an hour, gr. xv.; if required, gr. xv. were given at the end of the third hour. It sometimes caused slight sweating and slight cardiac depression. It gave rise to no gastric disturbances. Temperature fell one to three degrees and staid down one to eight hours. The antipyrin was used in twelve cases.

Previous Attacks of Pneumonia.—In eleven cases there was a well-marked history of a previous pneumonia. In one case there was a history of two previous attacks.

Death.—The days on which patients died most frequently were as follows; eighth day, 17 cases; sixth day, 13 cases; fifth day, 12 cases; ninth day, 10 cases; fourth, seventh, and tenth days, 9 cases each.

In one case the patient, while convalescing, suddenly cried out, complained of great pain in the chest and dyspnœa, and rapidly became cyanosed. Oxygen caused the cyanosis to disappear. The heart was stimulated, but the patient died in two and a half hours of heart-failure.

Autopsy showed a clot in the pulmonary artery to be the cause of death. One patient died of purpura hemorrhagica, which came on the seventh day of the pneumonia. He died of hemorrhage, losing twenty ounces of blood by uncontrollable epistaxis in a week.

TIME OF ADMITTANCE TO THE HOSPITAL.—Average time of all cases, 5.4 day of disease; average time in uncomplicated cases, 4 day of disease; average time in complicated cases, 6.2 day of disease.

GENERAL RESULTS.—According to age:

	Complicated.		Uncomplicated.	
	R.	D.	R.	D.
1–10 years	....	....	2	....
10–20 years	3	2	13	3
20–30 years	23	15	35	15
30–40 years	13	27	15	5
40–50 years	6	25	6	4
50–60 years	1	8	5	4
60–70 years	2	8	5	1
70–80 years	1	....	....	1

According to the class of case: Uncomplicated cases, 78, or 68.4 per cent. recovered; 36, or 31.5 per cent. died; complicated with pleurisy, 18, or 62 per cent. recovered; 11, or +37 per cent. died; cases with other complications, 34, or 31 per cent. recovered; 75, or 68.8 per cent. died; of all cases, +51 per cent. recovered: 48 per cent. died; per cent., excluding those moribund on admission, 62.31 recovered; 37.69 died.

I attribute the high death-rate to the following causes: the large number of complicated cases, the large number of those past treatment and moribund on admission, the patients being alcoholics as a rule, and finally the late day of admission to the hospital.

A SIMPLE AND EFFICIENT SURGICAL OPERATION FOR INCOMPLETE LACERATED PERINEUM.[1]

By W. GILL WYLIE, M.D.,

PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC, GYNECOLOGIST TO BELLEVUE HOSPITAL, NEW YORK, ETC.

I WILL not attempt to give a complete essay upon this subject, but will endeavor to bring out certain points, a knowledge of which is essential to a clear understanding of the operation which I will describe. It is meant for the secondary operation on the perineum, not the immediate. The names of Dieffenbach, Langenbeck, Baker Brown, Sims, Simon, and Emmet are all connected with improvements in this method of operating, and the works of Savage and Hart on the anatomy of the female pelvis have made clear doubtful points about the structure of the perineum.

While an interne at the Woman's Hospital, twelve years ago, I saw several cases that had been operated on for laceration of the perineum, admitted for a second operation on account of the skin and mucous membrane stretching to such an extent as to form merely a thin covering over the rectocele and prolapsed organs behind it. I made drawings of several of these cases, one of which I still happen to have. For years I thought that failure in these cases had been due to the fact that the operator had not cut away enough tissue and put in his sutures deep enough. I did not recognize the fact that the old crescent-shaped denuded surface, which was made to include a large part of the labia and skin, only reunited the superficial and everted part of the perineum. Simon improved upon this by denuding a triangular strip upon the rectocele; and Dr. Emmet improved on this when he introduced the clover-leaf denuded surface; but both of these leave undenuded the retracted edges of the pubo-coccygeus muscle and pelvic fascia in the angles depressed on either side of the rectocele.

Five years ago I adopted a plan of operating, which I think is an improvement on either Simon's or Dr. Emmet's operation, and I have been teaching this operation at the Polyclinic and at Bellevue for the past three years. It is simpler, and, I think, secures better results than Dr. Emmet's last new operation.

I accept with slight modification Hart's views as to the manner in which the uterus is sustained in the pelvis, and also that the perineum does not directly sustain the uterus in position, but under great intra-abdominal pressure it is a support to the pubic segment, and thus limits prolapse of the pelvic contents. The best proof that it only indirectly affects the position of the uterus is, that when the perineum is completely divided so that fecal matter escapes voluntarily, the uterus, as a rule, will be found in about its normal position. In seven cases of complete laceration operated upon by myself in the past two years, in five the uterus was in good position, and in only one was there retroversion and prolapsus. In the remaining case the uterus was somewhat prolapsed, but not retroverted. The escape of fecal matter was the only complaint. I know of one woman who has borne five children with the rectum and the vagina torn through within an inch of the cervix uteri.

My observations and study long ago led me to think that one of the chief functions of the perineum is not, as Dr. Emmet expresses it, to sustain the rectum—for when the perineum is completely destroyed the rectum remains in place—but to enable the rectum and anus to perform their functions, and not allow the intra-abdominal force necessarily exerted to empty the rectum, to disturb the equilibrium of the pelvic organs and overstretch the pelvic fascia and ligaments. Excepting during expulsion of the child, the greatest force (intra-abdominal) that disturbs and displaces the pelvic organs is straining at stool. It is this force which stretches the ligaments, and when, as it so frequently is in women, greatly increased by constipation, causes relaxation of the perineum even when it has not been lacerated. And it is this force that causes rectocele, cystocele, and hernia of the organs of generation. Standing and walking may cause pelvic congestion, and when prolapse is well advanced, may add to it; but the intra-abdominal force caused by the erect posture is insignificant compared with straining at stool, for the pelvic and abdominal organs are all suspended independently of the perineum, and downward pressure from the diaphragm falls mainly on and in front of the pelvic bone.

Just after the birth of the child the pelvic ligaments and perineum are relaxed and yielding, but the abdominal walls are also relaxed and intra-abdominal pressure is for some weeks very slight.

To make plain the reasons for doing the operation as I propose, I usually describe the perineum as the movable point of attachment for the transversus perinæi, the bulbo cavernosus, the sphincter ani, levator ani, and some of the pelvic fascia, and also as the movable point of attachment for the anus and lower end of the rectum, and the lower end of the posterior wall of the vagina. It is composed chiefly of firm connective tissue, such as forms the ligaments of muscles in other parts of the body; and as consisting of two parts, the outer or superficial, and the deeper or inner part. Externally we have the transversus perinæi, the bulbo-cavernosus and external sphincter ani and perineal fascia; internally we have the levator ani, some of its fibres forming the internal sphincter ani, and the pelvic fascia which sweep down from the sides of the pelvis and help to form and strengthen the pelvic floor, and make with the fibres of the levator ani a firm ligamentous band at and in front of the lower end of the rectum, just where it joins the anus. It is this band which, being pulled up by the action of the levator ani, deflects the fecal matter backward and outward through the anus, as it is forced down the curve of the sacrum by the contraction of the gut and the compression of the intra-abdominal force exerted by the diaphragm and abdominal muscles. This ligamentous band not only prevents the fecal matter from being forced for-

[1] Read before the Medical Society of the County of New York, March 23, 1885.

ward out through the vaginal outlet, carrying with it the posterior wall of the vagina, thus forming a rectocele, and, by dragging on the posterior vaginal wall, tending to retrovert the uterus by pulling the cervix downward and forward, but it sustains the anterior wall of the vagina and bladder when forcibly pushed downward by severe intra-abdominal pressure, such as is exerted in straining at stool. The external perineum may be torn and cause little or no trouble, but when the inner part of the perineum, where the rectum merges into the anus, is torn or much relaxed, while the sphincter ani remains intact, then we have perversion of the immense intra-abdominal force needed to expel the fecal matter.

The muscular fibres of the pubo-coccygeus muscle that should encircle the vagina, united in front of the rectum and into the anus, are separated and the pelvic fascia are torn loose; thus the rectum is forced forward and downward, and we have rectocele; and the anterior wall is gradually overstretched and forced out through the open vagina, forming in time a rectocele and true hernia. When the perineum and sphincter ani are completely severed, then the fecal matter passively escapes, and we have no rectocele and very little prolapse.

When both the external and internal parts of the perineum are partially torn, there will be in time eversion of the lower end of the vagina, the ostium being everted and rolled out, while the inner part of the perineum is retracted laterally, forming the deep angles on either side of the rectocele.

In restoring the perineum, we must denude these depressed angles and insert our sutures so as to bring the retracted edges of the pubo-coccygeus and pelvic fascia into apposition up over the rectocele, otherwise we merely partially reunite this band that directs the action of the rectum; and where there is a real necessity for an operation to restore the perineum, we make a failure. The screen of mucous membrane and skin will look well for a while, but only lasts a short time.

I do not agree with Dr. Emmet when he says that the tearing is transverse, and not from before backward. I think that the usual tear starts by the tissues in front of the muscular wall of the anus separating, and then, instead of tearing through into the anus and rectum, the tissues tear laterally around the end of the vagina and anus, thus separating the attachment of the levator ani and pelvic fascia which holds in place the end of the vagina and anus; this explains why the deep scars are usually to one side or other of the rectocele. The anus and lower end of the vagina are thus partly torn loose from the levator ani, which, when torn, retracts laterally and inward, while the vagina and anus are prolapsed and the vagina everted.

My operation consists in denuding, not the skin or tissues covering the labia, but the mucous membrane that once formed the ostium vaginæ only as high as the old caruncles, laterally and gradually extending the denudation upward for an inch to an inch and a half in the vagina, going laterally so as to include the depressed angles on either side of the rectocele in these angles, removing the mucous membrane and connective tissue until firm white tissue is reached, and up over the rectocele to the opposite side, but only taking off the mucous membrane over the elevated part of the rectocele, so as not to injure the muscular structure of the vagina. The denuded surface, when completed and spread out, instead of being crescent-shaped or triangular, or like a clover leaf, is nearly square, with its longer axis extended up the vagina, except where the rectocele is large, then it may have its long axis running from side to side. Now the sutures are put into the superficial perineum in the same way as in the old operation, as was done by Dr. Sims thirty years ago; the third or fourth suture usually being inserted within the ostium vaginæ, but the three or four last ones are entered within the vagina and passed from the right side, dipping deep laterally, completely under the denuded angle and under the denuded surface of the rectocele to its centre; then the needle is re-entered at the same place in the centre of the rectocele and carried completely under the depressed denuded angle of the left side, and brought out in the side of the vagina opposite its point of entrance. The last one is passed in the same way and made to include the edge of the undenuded vagina, so that, when it is tightened, no undenuded surface is left in the vagina.

After all the sutures are inserted, usually numbering six or eight, I then thoroughly stretch the sphincter ani; this relieves tension in that direction, lessens the risk of troublesome hemorrhoids and fissures, and when the sutures are tightened the external perineum is drawn upward and inward, the most prominent part being that next to the rectum.

Before the sutures are introduced, the rectocele presents a convex surface, but when silver wire is used, after being inserted and the ends pulled upon, as the depressed angles are more fixed than the movable displaced rectocele, it will be depressed to the level of the angles and present a concave surface in place of the convex surface, and usually the sutures can be tightened and closed with very little tension at any one point.

In old cases of long standing, where the tissues are infiltrated and more or less atrophied, the tension is considerable, but dilatation of the sphincter relieves this tension and enables you to close the edges and bring the angles well together over the top of the depressed rectocele.

Of course, before operating the patient is carefully prepared by curing up any uterine disease existing, and the general circulation of the parts improved by the use of glycerine and alum pledgets. The vagina is always well washed with a solution 1 to 5,000 mercuric bichloride, and antiseptics used for sponges, hands, and instruments. After the operation is finished about twenty grains of iodoform are powdered over the sutures. Each time that the patient passes water the parts are washed with a weak solution, 1 to 1,000, mercuric bichloride, and fresh iodoform put on.

No catheter is used exceptwhen the patient is unable to pass her urine. The bowels in all cases are made to move by mild laxatives once a day. No bandage is put about the knees, and the patient is allowed food as she wishes it. In cases of pain, morphine is given. I sometimes have twenty successive cases without having an accident of any kind, or without seeing any pus or even swelling to any extent. I attribute this largely to cleanliness, the use of iodoform, and to the dilatation of the rectum.

This operation is efficient in restoring the perineum when it is relaxed or when the tear is submucous, and when carefully done it will successfully close the perineum when the sphincters are completely severed. Except where the vagina is lacerated very extensively, I rarely use any other than silver sutures passed from side to side and twisted together in the vagina. In old women with complete procidentia, after restoring the cervix, which in such cases is often lacerated, and where the anterior wall is excessively relaxed and stretched, I may carefully denude it and sew in a fold with catgut sutures; at the same time I restore the perineum as I would for laceration, but as the vagina is no longer to be used, I extend the denudation higher on the sides and further up on the posterior wall, so as to almost entirely occlude it. In some of these cases the tissues have so completely atrophied and degenerated, that they may give way unless the patient is kept recumbent for several weeks after the operation. In young women who may bear children I am careful in denuding the tissues, and do not extend the raw surface but very slightly above the retracted angles on the sides of the vagina, for if we destroy much tissue the next child will be sure to tear the perineum. I prefer silver wire, and always take interrupted sutures. Since we understand the importance of cleanliness and the proper use of antiseptics, either silk, gut of silkworm, or even good catgut will give good results.

I prefer a straight, round, pointed sewing-needle about an inch and a half long, which with Sims' needle-forceps can be readily passed. I enter the needle close to the undenuded surface and carry it well into the tissues, and take pains to see that it passes beneath the depressed angles and gets a hold in the retracted muscles or fascia; with the index-finger in the rectum the point of the needle is easily guided, and the fascia when caught up can be plainly felt on the stretch.

For dissecting the mucous membrane, I use a good pair of dissecting-forceps in place of the orthodox tenaculum, and I take pains to see that all loose cellular tissue is removed, so that union of firm tissue is secured where the ligaments and muscles have been torn.

The stitches are removed on the tenth day, and the patient allowed to sit up four or five days later, but is instructed to take care for at least six weeks. Intercourse too soon after the operation may tear or overstretch the perineum.

Regarding the perineum as the movable point of attachment for the transversus perinæi, the bulbo-cavernosus, the sphincter ani, levator ani, and some of the pelvic fascia, and also as the movable point of attachment for the anus and lower end of the rectum, and the lower end of the posterior wall of the vagina, the conclusions are:

First.—As a rule, when the perineum is completely severed so that the fecal matter escapes passively, the position of the uterus is not affected.

Second.—The external or lower part of the perineum may be torn to a considerable extent and the position of the uterus will not be affected.

Third.—When the inner and upper part of the perineum is torn or overstretched and relaxed, prolapse of the posterior and anterior vaginal walls will take place, and in time the uterus is retroverted, prolapsed, and may be forced out of the pelvis.

Fourth.—The explanation is that when that part of the perineum formed by the fibres of the levator ani and pelvic fascia, where they encircle and are attached to the lower end of the vagina and anus, are torn apart, and the lower end of the vagina and the upper part of the anus are loosened so that they are not held up and elevated when intra-abdominal force is exerted, as in straining at stool, both are forced out through the vaginal outlet, and they pull and drag down the uterus, and in time result in hernia of the pelvic organs.

Fifth.—In operating to restore the parts, we should aim to reunite the separated edges of the levator ani and pelvic fascia, and fix them to and in front of the lower end of the vagina and the anus, and lower end of the rectum.

Sixth.—This can be done efficiently only by denuding the retracted tissues on either side of the rectocele and uniting them over the rectocele. As the most important laceration is within the ostium vaginæ, to reach these tissues the operation must be within the vagina; and to secure good apposition and to avoid dragging down and adding to the tension, most of the sutures should be passed within the vagina from side to side.

Anecdote of Malgaigne.—Professor Malgaigne was one day examining a candidate upon his doctorate thesis, and was annoyed at the very bad replies and ignorance of the student. "Well," he cried at last, impatiently, "make me one good answer; can you tell me what it is to create?" "To create," said the young man, readily, "it is to make something out of nothing." "Correct, monsieur, and in proof of it we are now going to create you a doctor." The application of this will be seen during the present commencement months.

A New Initial Sign of Tabes. — Hyperæsthesia, complete or insular, of the cutaneous distribution of the plexus pudendo-hæmorrhoidalis, and frequently of the plexus coccygeus is a never-failing initial sign of tabes dorsalis, according to Dr. Wm. Th. von Renz.

Reports of Hospitals.

ALBANY HOSPITAL, ALBANY, N. Y.

Ovariotomy, Performed by Mr. Lawson Tait.

Reported by ALBERT VAN DER VEER, M.D, and JAMES P. BOYD, M.D.

The patient was thirty-three years of age, and had been subject to fits for upward of nineteen years. Up to the time of puberty she was a healthy girl, but during the past twelve years her general health had been very bad. The fits in this case, Mr. Tait thought, were clearly hysterical in character, and not epileptic, for the patient had not injured herself in any way during an attack, and an epileptic usually does. Neither did she become drowsy after an attack, as is inevitably the case in epilepsy. The history showed that the fits always came on before a menstrual period, and that the periods were fairly regular, the flow being rather under than above the usual quantity.

The chief symptom in the case was the intense pain which the patient experienced previous to the period, and which was relieved when the flow was established. Pelvic examination showed that the uterus was infantile and anteflexed, as is usual in such cases. The left ovary could not be felt, while the right was enlarged and apparently cystic. Mr. Tait said that the case was, without doubt, one such as is frequently met in England, where the patient's life from the beginning to the end of menstruation is one long agony. This woman consented readily to an operation when its nature had been explained to her, and nothing, the operator said, should prevent a surgeon from giving relief by the knife in such a case. In her present condition she was fully as sterile as she would be when the ovaries were removed, so that this objection could have no force.

September 11, 1884.—The patient was etherized and the operation begun. An incision, two and one-half inches in length, was made in the abdomen, just above the symphysis pubis in the median line, and the ovaries and tubes removed. The right ovary was found to have undergone cystic degeneration, while the left was small and contracted. To the left ovary Mr. Tait attributed the patient's trouble. The Fallopian tubes were not diseased. The operation lasted ten minutes; wound united with silk sutures and dressed with Gamgee pads and adhesive plaster. After the operation the patient's condition continued favorable until the end of the second day, when the abdomen was so greatly distended as to cause suffering. Enemata of spirit of turpentine were ordered, and in the course of a few hours the bowels moved freely, and great relief was experienced. On the sixth day all the stitches but one were removed. The last stitch was removed on the seventh day, and as it was removed a small quantity of pus followed. A large abscess was found in the line of the incision, and retarded the patient's recovery considerably. The abscess was treated with the "red wash" recommended by Mr. Tait, and also with zinc ointment. The temperature was 101° F. on the fifth day; on the other days during the first week it varied from 99° to 100° F. The pulse was variable. At the end of a month the patient was able to walk around, and the wound soon after was completely healed. During the time that the patient was confined to the bed there were no attacks resembling those of epilepsy. She was hysterical however. About six weeks after the operation, and a short time previous to her departure from the hospital, the patient had a convulsion, followed by complete loss of consciousness. This was the only one of the kind observed during the time that she was in the hospital.

Two Cases of Epileptiform Tic have recently been reported cured by nitro-glycerine.

ST. PETER'S HOSPITAL, ALBANY, N. Y.

Solid Tumor of the Ovary—Uterine Myoma—Abdominal Section Performed by Mr. Lawson Tait—Recovery.

Reported by ALBERT VAN DER VEER, M.D., and JAMES P. BOYD, M.D.

The patient was thirty-one years of age, unmarried, and had enjoyed good health until she reached her seventeenth year, when she was sent to Bellevue Hospital, New York, on account of an attack of pneumonia. She remained in the hospital three months. After leaving the hospital the menstruation was irregular and profuse. She was able to do housework, and did not seek medical advice until about eight years afterward, when she was again admitted to Bellevue Hospital. At this time frequent hemorrhages from the vagina had prostrated her. In the winter of 1881 the patient was in the Albany Hospital, and the principal symptoms at the time of admission were severe abdominal pain and hemorrhage.

Examination upon the day of the operation, September 10, 1884, showed that she had a large bilobed tumor, the parts of which were of unequal size. The larger mass was thought to be a cystic ovary, and the smaller mass on the left a myoma of the uterus—possibly two large myomata. Mr. Tait said that he had no hesitation in operating upon this case, although he had some doubts as to the propriety of conducting such operations in a crowded room. He had never before operated in the presence of more than a dozen persons, and should this patient do poorly he would be inclined to lay it to the atmosphere in which the operation was performed.

Mr. Tait here began the operation at 4.42 P.M., assisted by Drs. Van der Veer and Boyd. After opening the abdominal cavity, he announced that the case was one of solid ovarian tumor and of uterine myoma, and proceeded to remove both, with the uterus. The operation was finished at 5.24 P.M., making the time from the first incision to the conclusion of stitching up the wound, forty-two minutes. The pedicle was treated by Tait's circular wire-clamp. The wound was dressed with simple Gamgee pads made of absorbent cotton covered with carbolized gauze. Two of these were placed over the wound, and held in place by a cotton bandage passed around the patient's waist.

After the operation the patient's condition was favorable until about 10 P.M., when there was a severe hemorrhage, from the vagina apparently. About this time a catheter was introduced, and the urine drawn from the bladder was found to be mixed with blood. Through the prompt and efficient measures adopted by the house physicians, Drs. Flynn and Melick, the patient rallied, although when they began the use of the hypodermic injections of whiskey her pulse was imperceptible, and the respirations about forty-two. At 4.30 A.M., September 11, 1884, the patient desired to empty the bladder; a catheter was introduced, but no urine was found. At 10 A.M., September 11, 1884, the patient was seen by Mr. Tait and Dr. Boyd. After reading the house physician's report, Mr. Tait concluded that a portion of the bladder had been constricted by the clamp. A careful examination of the pedicle and abdominal wound revealed a satisfactory condition of affairs. Examination of the vulva revealed the fact that blood was slowly flowing from the urethra, and a catheter passed into the bladder came in contact with clots.

Mr. Tait remarked that the patient's recovery would be retarded by the accident, as a fistula of the bladder would result, but that even with this complication she would get well. He said that the accident had occurred in two of his operations in England. The bladder was washed out twice a day with a weak solution of carbolic acid, and a soft catheter was allowed to remain in the urethra.

After a few days a solution of boracic acid was substituted for the carbolic acid.

On the fourth day after the operation a bloody fluid of a decided ammoniacal odor was noticed oozing near the pedicle. There was no tympanites at any time. The stitches were removed on the sixth and seventh days after the operation, and the wound was found to be perfectly healed as far as the clamp. The only dressing used was that of absorbent cotton and carbolized gauze. The clamp was removed on the eleventh day. Long before this time the urine flowed freely through the opening in the abdominal wall. As the remnants of the pedicle were removed a large funnel-shaped cavity came into view, at the bottom of which was the fistula.

The temperature reached 102° F. on the day after the operation; also on the third, fourth, and fifth days. On the fourteenth day 103° F. was recorded. The pulse was above 100 for the seven days succeeding the operation. On November 30, 1884, the fistula was entirely healed, and the patient had perfect control of the bladder. Examination of the abdomen revealed a firm cicatrix extending from near the umbilicus to the symphysis pubis, and no trace of the fistula could be discovered.

Clinical Department.

POTASSIUM IODIDE RASH SIMULATING VARIOLA.

In a report made to the Health Office of the District of Columbia, for the year ending June 30, 1882, Dr. Llewellyn Eliot, of Washington, made a statement to the effect that many subjects are unable to take even the smallest quantity of potassium iodide without experiencing symptoms of an identical character to those of small-pox. This assertion was called in question at the time by many physicians of experience, and Dr. Eliot now reports the following case in its support: "On March 2, 1884, he was called to attend a recently married woman, nineteen years of age, suffering from hemoptysis. This was controlled by gallic and aromatic sulphuric acids, and two days later, there being some pleuritic pains on the left side, a mixture was ordered containing sixteen grains of iodide of potassium in an ounce of mucilage of gum acacia, of which a teaspoonful was to be taken every two hours. This was at one o'clock in the afternoon. At six she complained of pains in the lower jaw, and by midnight had the coryza, injected conjunctivæ, puffiness of the face, severe headache, aching of the body, especially in the back, soreness of the throat, and the appearance of red spots over the face. The red spots increased in prominence in a few hours, just as occurs in small-pox. Careful inquiries made the following morning failed to show exposure to variola, and the iodide was accordingly discontinued, and one-fourth grain sulphate of morphine given, together with hot whiskey. At nine o'clock that evening the pains had ceased, and the eruption was fading, and two days later had entirely disappeared. The symptoms of iodism followed the second dose, when but four grains had been taken."

ABSCESS OF THE LIVER.

Dr. Frank Cary, of Chicago, sends the following report of a case occurring in the service of Dr. J. N. Danforth, at St. Luke's Free Hospital, in that city: "The case is somewhat similar to one presented by Dr. Peabody, at a recent meeting of the New York Pathological Society, and reported in The Medical Record, January 3, 1885. A stone-cutter, fifty-five years of age, of temperate habits, was admitted to hospital on September 1, 1884, said to be suffering from typhoid fever. He had been in apparently perfect health up to within three

weeks, when he began to suffer from headache, loss of appetite, and profuse diarrhœa, but he had had no chills. On admission there was no tenderness over the abdomen; the temperature was normal, but the patient was greatly exhausted. On the second day the temperature rose to 103°, at 6 P.M., falling to the normal on the following morning. It then rose again gradually until six o'clock in the evening, when the patient died, apparently from exhaustion. At the autopsy, made some twelve hours after death, the liver was found to be completely riddled with abscesses, there being no less than twenty-four, varying in size from a pigeon's to a goose's egg. The organ was about normal in size, and was firmly adherent to the diaphragm, anterior abdominal wall, and colon, different abscesses pointing in these several directions. The colon from the ileo-cæcal valve to the sigmoid flexure was a mass of confluent ulcerations, so that the mucous membrane was almost entirely destroyed. The rest of the intestinal tract was normal. The spleen was neither enlarged nor softened. The gall-bladder was apparently normal. Dr. Cary is inclined to agree with Dr. Peabody in regarding the relation between the intestinal ulcers and the abscesses of the liver as one of cause and effect, although he states that Coats, in his "Pathology," does not regard the manner as one beyond question. The patient had never lived in the tropics, and had for years been a resident of Chicago."

SYMMETRICAL DRY GANGRENE.

Dr. J. W. Flynn, of this city, writes: "About six years ago I was treating a man, seventy-five years of age, who was suffering from capillary bronchitis, and was doing nicely when gangrenous changes of the distal phalanges of both hands and feet made their appearance, and the lines of demarcation showed in about ten days. After this the patient rapidly failed, and died in comatose condition."

Progress of Medical Science.

Sleeplessness.—Sleep is a perfectly natural function. It is not a negative act, but a positive process. Herein lies the difference between real sleep and the poison-induced torpor which mimics the state of physiological rest. We ought to be able to sleep at will. Napoleon and many busy men developed the power of self-induced sleep to such an extent as to be able to rest whenever and wherever they pleased, for longer or shorter periods, as the conditions admitted. We have been led to believe that Mr. Gladstone at one time possessed this faculty. If that be so, his recent insomnia must be assumed to have been the result of such intense brain-worry as inhibited the control of the will; or there may, of course, be physical causes which render the apparatus of the cerebral blood-supply less manageable by the nerve-centres. In any case, it is much to be deplored that, in the study and treatment of insomnia, the profession generally does not more clearly and constantly keep in memory that what we call sleeplessness is really wakefulness, and that before it is justifiable to resort to the use of stupefying drugs the precise cause of disturbance should be clearly made out. This, of course, takes time, and involves a scientific testing of the relative excitabilities of the sense-organs, central or radial and peripheral. The discovery of the cause, however, affords ample recompense for the trouble of searching for it. With the sphygmograph and a few test appliances, such as Galton's whistle, an optometer, and other instruments, the recognition of the form and cause of sleeplessness can be made in a brief space, and then, and then *only* we protest, it can be scientifically —*i.e.*, physiologically— treated.— *Lancet*, January 10, 1885.

Artificial Anus Cured by Enterotomy.—Dr. Cannizzaro has reported the following case: S. P——, aged sixty-seven, for some years had had a reducible right inguinal hernia. Symptoms of strangulation supervened, and a surgeon, after ineffectually applying taxis, advised operation. The patient objecting, the hernial coverings sloughed, and an artificial anus was established in the right groin. When Dr. Cannizzaro operated on the 1st of last October he found the septum or spur very well marked. Having grasped it in its whole depth within the blades of the enterotome, he tightened the screw until the patient complained of pain in the part and at the epigastrium. The instrument was immobilized with a spica bandage and compress. During the first day the patient was much depressed, and inclined to vomit. The dressing, changed each day, contained fecal matter; each day also the screw was tightened until the patient complained of pain. Chicken-broth, eggs, and wine were taken freely. During the fifth night the bowels acted abundantly twice and naturally. On the sixth and seventh days very little fecal matter was found around the dressing, and on the eighth day the enterotome was observed to be very movable. It could not then be detached, but it came away with the dressing on the ninth day after operation. The wound was then washed with carbolized water, its surroundings brushed with collodion, and a compressing bandage applied. From this date the patient continued to evacuate per anum; in reapplying the bandage daily, care was taken to approximate the edges of the wound, which gradually healed, the patient leaving the hospital cured, in excellent health, on the 15th of November, just forty-five days after the operation.—*Rivista Internazionale di Medicina e Chirurgia.*

The Pathology of Cheyne-Stokes Breathing.—Some histological alterations in the bulb and pneumogastric nerves, to which changes he attributes the phenomena of Cheyne-Stokes respiration, have been recently discovered by Tizzoni (*Lancet*, January 31, 1885). This mode of respiratory rhythm consists in the presence of a prolonged pause followed by respiratory movements, at first slow and superficial, but gradually rising in frequency and increasing in depth, again slowly to decrease. So much misunderstanding has arisen on the subject of what is and what is not meant by this-named mode of respiratory rhythm that Tizzoni has done well to state precisely what it is that he meant. In one of his cases there was organic heart disease, and the respiratory phenomena lasted forty days. At the autopsy chronic inflammatory changes were found ascending the vagi, with blood, extravasation into the lymphatic spaces of the perineurium and endoneurium. On the left side only the peripheral portion of the nerve was affected, while the right nerve was altered along the whole of its course, even to its origin. In the bulb the changes existed in the form of small foci, and were also more marked on the right side. The point where the alterations were most prominent was beneath the ependyma over the longitudinal furrow of the calamus scriptorius. In a second case, which was one of uræmia, the phenomena were observed for several days. The vagi were normal, but the superior half of the medulla oblongata presented lesions similar to those just described, though less pronounced and symmetrical.

Deaths from Lightning in France.—Lightning has killed 4,609 persons in France alone since 1835. An equal number have been seriously, though not fatally, wounded, and five times as many struck. The hot years were the most fatal, and these are remarkable as having been the best wine seasons. There has not been a single death from lightning in Paris or the Department of the Seine since 1864, though there have been many violent storms there during that time.—*Bulletin de l'Association Scientifique de France.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, March 28, 1885.

CORROSIVE SUBLIMATE IN SURGERY AND OBSTETRICS.

A CONSIDERABLE amount of conflicting evidence now exists as to the advantages of corrosive sublimate in surgery and obstetrics. An important contribution to the subject has been made by Dr. Max Schede, in *Volkmann's Klinische Vorträge*, No. 251.

After an experience at Halle and Berlin, in which Schede had been thoroughly converted to the principles of antiseptic surgery, he was called about four years ago to take charge of the general hospital at Hamburg. The hospital building here is about fifty years old, many of the rooms are low and dark, the wards are overcrowded, so that often patients can be allowed only six hundred to eight hundred cubic feet of air, when they ought to have one thousand eight hundred. Near by is a dead-house in which a very large number of bodies are dissected. Some two or three hundred cases of phlegmonous erysipelas are admitted to the wards yearly. There is in the building a department for skin diseases, cancer, and syphilis. The hospital itself is a very large one, admitting over a thousand cases into the surgical department annually, while the number of operations is consequently proportionately great.

Previous to the introduction of Listerism by Schede's predecessor, the number of septic accidents and cases of erysipelas was very large. Under Listerism a marked improvement took place, but it did not accomplish enough to satisfy the new director.

He first began a systematic attempt to organize the surgical service, and to teach all the attendants the need of absolute cleanliness and asepis. Coming to Hamburg at the time of the iodoform era in surgery, Schede at once introduced the iodoform treatment in all its details. But he was much disappointed in its results. Although he had some brilliant successes, the iodoform treatment often failed to prevent septic complications, while erysipelas increased in the wards very rapidly. Schede does not say that iodoform causes erysipelas, but he is decidedly of the opinion that it does not prevent it. The iodoform treatment was, therefore, abandoned as a failure, and corrosive sublimate was introduced. This he has now used for two years and a half. The results obtained have been most brilliant and satisfactory, and Schede now comes forward as an enthusiastic advocate of the sublimate treatment of wounds.

A careful description of the technique of his method is given in the monograph to which we have referred. We cannot attempt here to follow him in all the details. He has for use two sublimate solutions, the stronger consisting of corrosive sublimate and water, 1 to 1,000, and the weaker, 1 to 5,000. The first is used to disinfect the hands, the skin of the patients, sponges, drainage-tubes, and all wounds which are to be closed. The second is used for irrigating wounds and contiguous healthy tissues. During operations, the parts are generally irrigated with the 1 to 1,000 solution. When large surfaces are to be irrigated, however, he uses the weaker solution, for fear of toxic effects. The materials employed for dressing are peat (turf moss—*sphagnum*), occasionally sand, glass wool, sublimate gauze, sublimate wadding, and sublimate catgut. The peat is cleansed and then soaked for some hours in 1 to 500 solution of sublimate. After this it is squeezed out with the hands and placed between layers of sublimate gauze. The edges of the gauze are stitched together so as to make pads of various sizes. A number of these pads are made up every day and stored away and kept moist. Sublimate wadding and gauze are prepared by soaking the substances in a solution of sublimate 1 part, water 190 parts, and glycerine 10 parts. They are then wrung out in a machine and allowed to dry. The glass wool, of which Schede speaks in the highest terms, is prepared by soaking it in a one per cent. solution of sublimate. The sublimate catgut, which is also very highly praised, is made according to the method described by Kümmell. After the wound has been carefully cleansed and dried with a large sponge, it is covered with a layer of glass wool moistened with the strong sublimate solution, then with the peat pads, and firmly compressed with the gauze bandages. Open wounds are generally covered with three or four layers of gauze and then with the pads. For drainage, rubber tubes are exclusively used. Other forms have been tried and abandoned.

Concerning some of the special advantages of his method of treatment, Schede makes the following points:

1. The sublimate solutions are more efficacious and less dangerous than 5 per cent. carbolic acid solutions.

2. In severe wound infections, wound diphtheria, and gangrene, which call for very strong disinfecting agents, the sublimate solutions can be safely used. Even one per cent. solutions have been successfully and harmlessly applied to gangrenous wounds.

3. Sponges and wadding, soaked in 1 to 1,000 solutions, can be safely applied to ulcers, unhealthy, dirty, and granulating wounds, the applications being changed once or twice daily. For fungous and tuberculous processes, Schede considers the sublimate almost a specific, and better far than iodoform.

Appended to his article is a tabular statement showing the results of the sublimate treatment. There were in all 1,286 operations. In these, the wounds healed without suppuration in 935 cases; with suppuration in 278 cases; making a total of 1,222. In 9 cases there was incomplete healing, and in 64 cases, death.

Among special operations there were 25 ovariotomies, all healing without suppuration; 229 amputations, with 12 deaths; 30 resections of the knee, with 4 deaths, all from tuberculosis; 13 total extirpations of the uterus, with 1 death. The record is a remarkably good one in

many respects, and especially when it is considered that the work was done in an old and crowded hospital.

In conclusion, Schede discusses the dangers from absorption of the sublimate. He particularly refers to the report of the prosector, Herr Fränkel, who found diphtheritic entero-colitis, post mortem, in a number of cases, and attributed it to the mercury. To offset this, Schede reports four cases in which the same lesions were found after death, but in which the sublimate had not been used at all. He concludes that the diarrhœa and enteritis may be caused by sepsis. His cases certainly take away some of the force of Fränkel's observations. Schede believes that with proper precautions the sublimate wound treatment is safer than any other.

As evidence of the occasional danger from sublimate dressings, we may call attention to the facts collected in this city by Dr. Peabody, and published in THE RECORD of March 14th.

In this connection, also, we would refer to the alleged dangers of sublimate in the treatment of obstetrical cases. Auvard, in *L'Union Médicale*, refers to two fatal cases of sublimate poisoning as the result of intra uterine injections of sublimate solutions. Hofmeier also reports two cases of poisoning, of which one was fatal, and similar cases have been reported by Stadfeldt and Winter (THE MEDICAL RECORD, March 14, 1885, p. 291–2). One of the conclusions drawn by Auvard is, that the condition of the kidneys is a most important one to bear in mind, as a nephritis renders the patient more susceptible to the toxic effects of mercury.

Dr. W. Thorn has given an interesting review of this question in *Volkmann's Klin. Vorträge*, No. 250. He reports two fatal cases from the use of sublimate in obstetrics. He also gives the records of the Policlinic and Maternity service at Halle, during the periods of the use of carbolic acid and of sublimate, and believes that the records indicate the inferiority and danger of the latter substance.

He concludes that sublimate solutions should not be used to irrigate the vagina or uterus, either *inter partum* or *post partum*. In their place he would substitute the old carbolic injections. For disinfection of the external genitals, instruments, and operator, sublimate may be used. Dr. Thorn, in this, follows the views of Mikulicz, who claims to have shown that corrosive sublimate, when applied to exposed tissues, forms an albuminate of mercury, which has a feebler antiseptic power.

In opposition to Thorn's conclusions, it should be stated that, in Tarnier's clinic at the Paris Maternité, the sublimate has been found to be the most efficient disinfectant.

THE ELIMINATION OF TUBERCLE BACILLI BY THE SKIN.

SOME investigations recently undertaken by Dr. A. Severi, into one of the possible modes of contagion of tuberculosis (*Siomale Internazionale delle Scienze Mediche*, No. 1, 1885), are worthy of more than passing mention, by reason of their importance from a prophylactic point of view. The subjects of the investigations were three women, suffering in an advanced stage of phthisis, and whose sputa contained numbers of bacilli. The author's labors were first directed to a differentiation of tubercle bacilli from the micro-organisms found by Bizzozero in the epidermis of healthy individuals. The method employed was that used by the latter in his researches. The epidermis is delicately scraped off from various parts of the body, especially of the arms and the anterior part of the chest, and the scrapings are then heated on a glass slide, all fat particles are dissolved away by chloroform, and the residue is strained in the ordinary manner. To assure himself that no bacilli were deposited on the skin from the air, the author had the arm washed with hot water and soap, then with ether, and finally with a one per thousand sublimate solution. It was then dried with carbolized gauze, covered with rubber tissue washed in the sublimate solution, and over all a carbolized cotton dressing was applied. At the end of two or three days this dressing was removed, and the arm scraped in the manner above described with a knife washed in a five per cent. carbolic solution. In each instance Dr. Severi obtained the tubercle bacilli, and often in considerable numbers, especially after the patient had perspired much during the night. This fact that the bacilli were most numerous after profuse sweating led the author to the belief that they were probably eliminated through the sweat-glands. It is to be hoped that these investigations will be repeated, and, if the results announced by Severi are verified, it would seem to be the duty of the medical attendant to see that the night-clothes and the undergarments of phthisical patients are so heated as to effectually destroy the micro-organisms contained in them.

THE RELATIVE MERITS OF OPERATIONS FOR THE REMOVAL OF EPITHELIOMA OF THE TONGUE, TONSILS, AND PALATE.

THE discussion of the relative merits of the different operative procedures for the removal of the tongue, tonsils, and soft palate, has, in view of recent experience, more interest as applied to similar cases than to that of General Grant. Each operator makes his own plan, and is necessarily governed by the various conditions of disease in the particular case. It is fair to suppose, however, that in the present instance any plan of operation, whether involving section of the jaw in front of the masseter muscle, resection of the ramus, double or single, or division of the bone in any other part of its course might fail to secure the complete extirpation of the morbid growth.

In selecting a method to be adopted in General Grant's case, in the event of an operation being considered advisable, one of the consulting surgeons, Dr. Sands, expressed a preference for that proposed by Langenbeck, in which the jaw is divided on the side; and his opinion would doubtless have been endorsed by the other gentlemen in attendance.

ACCOMMODATIONS FOR THE CHRONIC INSANE.

IN the Eighteenth Annual Report of the Managers of the Hudson River State Hospital to the Legislature, is made a timely plea for an increase, in the eastern part of the State, of accommodations for the chronic insane. The suggestions made are, in brief, that the present buildings at Poughkeepsie should be wholly given up to female patients, and that new buildings, capable of accom-

modating at least fifteen hundred, should be erected for males on the eastern part of the same State property. Statistics show that there are at large throughout the State over forty-five hundred insane persons, outside of custodial institutions of any sort. The claim of the eastern counties to this special allotment of State bounty is based upon their excess of population over the western part of the State, their larger tax lists, and especially their present poverty of accommodations.

We regard this plea worthy of immediate attention at the hands of our law-makers. The establishment of such institutions as are proposed would relieve the pressure upon our present asylums. The latter are so overcrowded that proper distinction cannot be made in treatment between the acute and chronic cases. In this way the former speedily degenerate into the latter, and thus become a lasting burden to the community. If they could be properly cared for in the early stages of their malady, its progress might be greatly retarded, if not entirely checked. In the event of this latter happy result, they would be spared to us as useful members of the community, and the burden of public charity would be perceptibly lightened. For those beyond aid the new institutions would provide a more humane life. We hope that our Senators and Representatives at Albany will give the matter early consideration, and that thereon may follow prompt and decisive action.

UPTURNING THE STREETS.

It was hardly necessary to get the testimony of eminent physicians in order to establish the fact that an extensive upturning of the streets in summer would be injurious to the health of the city. This, however, is what the organ of one of our city's millionaires has, with painful elaboration, attempted to do, and with a very apparent purpose. Under the guise of opposing a cable railroad, medical testimony was obtained, of which the inference is that it would be dangerous to compel the telegraph companies to put their wires underground, as directed by law. The fact is that, while the extensive digging up of streets would be harmful, the making of narrow, shallow ditches for the reception of wires would probably be a perfectly safe procedure, especially if the city Board of Health were allowed some supervision.

Public opinion, public comfort, and public safety, to say nothing of æsthetics, demand that the linear incubus of electric wires which now hangs over us be removed. We trust that the medical profession will not be misled into expressions of opinion which will assist in unnecessarily postponing the execution of the law that provides for this removal.

FOREIGN PAUPERS AND LUNATICS.

The Report of the State Board of Charities for 1884 contains much of interest on the subject of foreign paupers and lunatics. The asylums are becoming crowded with these troublesome visitors, notwithstanding the law which directs that persons likely to become a public charge shall be returned at once to the countries from which they came. It is much easier, however, to slip through the lines at Castle Garden than to detect on the instant such probable public beneficiaries, and after immigrants once get out of sight of the officials there is little chance of sending them abroad again. Out of the thousands arriving last year at this port, quite a number would, no doubt, have come under the ban of the law, but only one hundred and fourteen in all were returned. Of these, sixty-four were lunatics, imbeciles, or feeble-minded, and the remainder blind, deaf and dumb, or otherwise infirm. Over half of this number came from England and Ireland, the rest coming mainly from the continent.

In addition to the large number of poor and insane persons arriving by the emigrant ships, a large number are yearly pushed across the Canadian line, where the facilities for exclusion are very meagre. When once on our soil they gravitate immediately to the asylums, poorhouses, and public institutions, crowding them to overflowing. The report states that the commitments last year were very numerous, and show a large increase from the preceding year. The expense in each case for the taxpayers averages $100 a year. It is stated that the laws governing the admission of this class of immigrants should be made much more rigorous, and, in order to help the matter, the Secretary of State intends to send circulars to all our consular representatives, directing them to make public the laws of this country providing for the immediate return of paupers and lunatics.

The proportion of foreign-born persons on the registers of public institutions is much larger than that of native-born, and will tend to become even larger unless stricter measures are soon adopted.

THE CONDITION OF GENERAL GRANT.

During the past week General Grant has been in a comparatively comfortable condition. The insomnia with which he has been affected has been controlled, so that he obtains, by the aid of anodynes, the normal amount of sleep. He has not lost flesh, and his powers of assimilation are not impaired.

At the weekly consultation, attended by Drs. J. H. Douglas, H. B. Sands, and George F. Shrady, it was decided that the local disease was still in abeyance, and that the area of ulceration had not perceptibly increased. Virtually the same stationary tendency was noted by Dr. Fordyce Barker, who has visited the distinguished patient at intervals during that period. The swelling under the right angle of the lower jaw is somewhat greater, but the gland in that situation is not more indurated, nor has it become more firmly fixed. The ulcerated surfaces in the throat and on the tongue are covered with a yellowish exudation, to which alternate applications of lime-water and a weak solution of permanganate of potash have been effectively made by Dr. Douglas.

The topical remedies employed have had their desired effect in reducing local irritation, and in perceptibly checking the progress of infiltration. There is no pain in swallowing. No fear at present is entertained of any sudden failure of the vital powers, nor of any encroachment of the ulcerative process upon the neighboring blood-vessels.

The General is able, with no other assistance than that of his cane, to walk about his rooms, ascending and descending the stairs, and was strong enough to enjoy an airing in his carriage during the fine afternoon of Wednesday.

News of the Week.

Is Scarlet Fever Communicated by a Third Healthy Person.—Dr. Simon Baruch of this city, writes: "In the valuable report of the proceedings of the Practitioners' Society, published in The Medical Record of March 14th, I am reported as saying that I 'did not think scarlet fever could be conveyed by a third healthy person, and quoted Henoch's statements of such a view.' This is an error, due doubtless to the necessary condensing of the remarks made, which I beg you to correct. I said that the question of the transmissibility of scarlatina through a third person is not by any means settled, as was demonstrated in a discussion of Henoch's paper on the subject in 1883 (*Berliner klin. Wochenschrift*, Nos. 24 and 25, 1883). Personally I have never experienced such a method of transmission. Acting upon the safe view, that it is possible, I have always adopted precautionary measures, which would lessen this possibility as much as lay in my power. The discussion above referred to was earnestly entered into by the Berlin Medical Society, in which Professor Henoch had offered a motion to appoint a committee of three or five members, to investigate the subject and to consider the propriety of asking the Government to adopt strict regulations with reference to the exclusion from school of children coming from infected houses. In the course of his argument in support of this motion, Professor Henoch said that the question of transmissibility of scarlatina by third healthy individuals is not decided, that most physicians have an instinctive feeling of its possibility, but that it cannot with certainty be proved or disproved. He also said that he was impelled to advocate stringent measures of exclusion from school, not because of this possibility, but because children from infected houses may visit school while in the incubation period, and thus spread the disease. Professor Henoch's motion failed to be adopted. The largest statistical information of which I am cognizant justifies the action of the Berlin Medical Society, which was prompted entirely by the doubtful aspect of the question. Dr. Kerschensteiner, a high medical official in Bavaria, said in an address before the Hygiene Ausstellung in Berlin, in 1883, that in an official practice of twenty years he has rarely known transmission through a healthy person, which fact induced him to bring the question before the Medical Society in Munich for discussion, with the result that most physicians, especially the busiest, can remember no case in which they or their assistants had conveyed the disease. And this view was confirmed by replies from a large number of Medical Societies in Bavaria. On the other hand, Dr. Axel Johannessen, in his prize essay on "Scarlet Fever of Norway," arranges the information obtained from a review of the records of all epidemics in Norway, from 1817–25 to 1878, and among other deductions claims that there is strongest proof that direct contagion is the most frequent; transmission through congregations of people, especially burial societies has occurred. But most important are the frequently produced evidences of transmission through healthy persons, and he mentions especially cases in which physicians transmitted the disease (*Journal für Kinderkrankheiten*, 1884). These recorded facts sustain me in the opinion expressed before the Practitioners' Society, that the questions of transmissibility of scarlet fever by healthy persons is still far from being settled. It is a serious hardship to a household when a number of children are prevented from attending school for many weeks because one child is ill with scarlatina. There are other questions connected with this subject of importance, especially to the practitioner himself, which I propose to discuss at some future time.

An Insane Asylum Investigated.—The State Insane Asylum at Lincoln, Neb., has recently been investigated by a committee appointed by the Legislature. It was found that the institution was overcrowded and badly managed in many ways. The present superintendent is retained in office, and a number of reforms in organization are enjoined.

The Cholera has reappeared at Toulon.

The Bovine Virus Question.—Our two correspondents present the subject of the dangers of bovine virus and their prevention from two different standpoints. They cover the whole question, and undoubtedly solve its difficulties theoretically; but the physician will ask, How am I to know who sells good virus, and how am I to make my patients keep their wounds clean and aseptic?

The "Index Medicus."—We take pleasure in announcing that Mr. George S. Davis, of Detroit, has undertaken to continue the publication of the *Index Medicus*, on the same general plan, and with the same regard to typographical accuracy and finish as heretofore.

Charity Hospital.—Dr. Richard G. Wiener has been appointed visiting physician to the above institution.

Cholera and Whitewash.—During the great cholera at Zanzibar, low down on the eastern African coast, in 1869, the first and most severely attacked were the negro slaves and slave-dealers, most of whom were also black. Next followed the Arabs and Hindoos, while the more careful whites were spared; so that the negroes came to the sage conclusion that the demon of cholera hated all the colored races and loved the whites. Hence they whitewashed themselves all over, and put on an unusually large quantity on their woolly heads, so that in looking down he might mistake them for whites. As this did no good, they took to wearing white instead of colored loin-cloths, and finally arrayed themselves completely in white cotton cloths, and slept in them. But the demon was not to be so easily deceived, and still went for the negroes.

Professor Ambrose L. Ranney has been appointed to the chair of nervous diseases in the medical department of the University of Vermont, made vacant by the resignation of Professor W. J. Morton. Professor Ranney will deliver a course of lectures each year in this field, in addition to his course upon anatomy.

The Cartwright Prize.—Essays in competition for the Cartwright Prize must be handed in to some member of the committee, on or before April 1, 1885. The members of the committee are Robert Abbe, M.D., 32 East Twentieth Street; Walter Mendelson, M.D., 209 West Forty-sixth Street; and R. W. Amidon, M.D., chairman, 18 West Twenty-first Street.

Dr. Spitzka's Article on the Lemniscus.—Dr. E. C. Spitzka writes: "Will you kindly permit me to offer the following correction of a foot-note published in connection with my article on the lemniscus in The Medical Record, November 1, 1884, p. 480. It is there stated that the excess of the ventral fissure of the myelon over the dorsal fissure, alone among mammals, is found with the porpoise. The same excess is noted in the cervical cord of the sea-lion (*Zalophus Gillespiei*), so that the statement would have to extend possibly to all the marine and littoral mammals. That this modification of fact only serves to strengthen the surmise expressed in the foot-note referred to is evident, as the seals present in a lesser degree the preponderance of axial over extremity muscles noted in the porpoise."

The Disposal of the Bodies of Convicts.—A convict, named Marcus Stone, committed suicide at the Connecticut State Prison, in Wethersfield, a short time since, and, according to the usual custom, word was sent to his relatives at Putnam that the body was at their disposal. They replied on a postal card, saying: "If you want to send the body on and pay all the expenses we will bury it. Otherwise let him be buried at Wethersfield." It is not stated what the prison authorities did under these circumstances, but they very probably turned the body over to the Yale College Medical School, as an old law of the State authorizes them to make such disposal of the bodies of convicts.

A Warning to Polo-Players and Roller-Skaters.—The death of a polo-player at Binghamton, not long since, from injuries received while playing a game, is a warning against one of the most dangerous pastimes now popular among the young men. It is not likely, however, that it will be heeded any more than the example of Joseph Cohen, one of the contestants in the recent roller-skating contest at Gilmore's Garden. The latter died a few days after the close of the race, from the exhaustion caused by the unusual strain upon a naturally weak constitution.

Convicted for Selling Prescriptions.—Howard Kenny, who has an office under the name of "Dr. Powell," at 66 Court Street, Brooklyn, was brought before the police court in that city a few days since, charged with selling prescriptions wrongfully. He advertised largely a specific which he sold for two dollars. He claimed to get the prescriptions from a Dr. Powell, of New York Mills, N. Y., and a Dr. Church, of New York City. He was unable to present a diploma, and the justice fined him ten dollars for violation of the Sanitary Code.

Cholera and Water Supply.—The City Board of Health has made an investigation of the sanitary condition of the tract of country drained by the Croton River and its tributaries. The result of the investigation shows no very alarming state of affairs. The Croton watershed embraces a district of not less than 339 square miles, traversed by a number of creeks and smaller streams beside the Croton River itself. The total population of the district is 22,000, or 59 to the square mile. The excreta from this population and its domestic animals finds its way more or less into the natural drains of the region and the running water-courses. Probably all of it is now destroyed before it reaches New York. Some possible sources of danger, however, exist. At two points on the Croton there are extensive condensed milk factories, one employing a hundred and the other over seventy-five hands, located on the very bank of the stream, that had privies for the use of the employees opening directly on the water. There is also a slaughter-house, where cattle were constantly killed, located on the bank, and all the offal and sewage went into the river. All along the stream and its tributaries are houses with sewerage arranged on the plan of the condensed milk factories above mentioned.

Ziemssen's Cyclopædia is being translated into Spanish and published at Madrid.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 19, 1885.

A. Jacobi, M.D., President, in the Chair.

THE TREATMENT OF PATIENTS IN THE TEMPLES OF ÆSCULAPIUS.

Professor Augustus C. Merriam, of Columbia College, New York, delivered an interesting lecture on the above subject, in which he gave a historical sketch of the methods of healing practised in those temples, especially at Athens and Epidoris, and revealed by Grecian excavations begun March 16, 1881. The speaker pictured the deep and abiding belief which the ancients had in the anger or malice of the gods, as a *cause* of disease, and also in the marvellous and miraculous *cure* of disease by some divinity.

The beginning of the art of medicine, in all times and among all peoples, was empiricism, based on the belief that all severe sicknesses were caused by the anger of some god or demon.

The faith of the people in the power of the gods of Æsculapius to cure disease was unlimited, and was represented by the saying of Plato, who declared that "we must not suppose that Æsculapius failed through ignorance, but that he deliberately withheld his power at times for the benefit of the race."

The writings of Solon, who mentions "the laying-on-of-hands," etc., of Pythagoras, who was a physician as well as philosopher, of Plato, of Aristophanes, and of other ancient Greeks, are all flavored with the belief in the influence and power of divinities.

Galen, it seems, was nearly free from superstition, yet he refers to the patrial god Æsculapius. Three hundred and twenty temples of Æsculapius were known to have existed in antiquity; those of Athens and Epidoris having been built about the end of the fifth century before Christ.

The speaker sprinkled his discourse with translations of inscriptions found upon slabs removed in recent excavations, some of which were highly amusing.

Dr. Alfred C. Post moved that a vote of thanks be tendered to Professor Merriam for his learned, interesting, and instructive discourse, and that a copy be requested for publication. Unanimously carried.

Dr. John C. Peters said that the subject of the lecture was one in which he had been greatly interested, and it was one which had also attracted the attention of other physicians, particularly the late Dr. John Watson, who wrote a remarkable paper on it. From the information which he had obtained, he had reached a conclusion not quite in accord with the impression given by Professor Merriam's remarks concerning the character of Hippocrates, who was the eighteenth in descent from Æsculapius, and who, as Dr. Peters believed could be established,

did not resort to any tricks or invoke the aid of divinities in the cure of diseases.

Hippocrates laid down the rule, first, that the remedy which cures a case will cure all other cases absolutely like it. As the cases which were absolutely alike were almost unknown, this was a principle which could have only an exceedingly limited application.

The next proposition given by Hippocrates was, that remedies which acted exactly opposite to a disease would cure it. It was not very remote when it was determined that this proposition had a limited application.

The next proposition was, that remedies which acted *nearly* opposite to the disease would cure it, and this extended the list of remedial agents. Finally, Hippocrates announced that some diseases were cured by remedies which acted in a way similar to the disease, and with all these classes of remedies he expected to be able to meet successfully the ills of mankind. Dr. Peters regarded Hippocrates as a man of remarkable erudition, and one who was equal with the philosophers and teachers with whom he was contemporaneous.

PROPOSED AMENDMENT TO THE CONSTITUTION.

Dr. V. P. Gibney offered a proposed amendment to the Constitution providing for a change in Article 6, Section 2, which will, if adopted, establish *eight* sections in the Academy.

The object is to gather the work of the profession around a common centre. The proposition will be acted upon at the next stated meeting.

The Academy then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 23, 1885.

Daniel Lewis, M.D., President, in the Chair.

Dr. W. Gill Wylie read a paper (see p. 345) entitled,

A SIMPLE AND EFFECTIVE SURGICAL OPERATION FOR INCOMPLETE LACERATION OF THE PERINEUM.

The discussion was opened by Dr. James B. Hunter, who said he had but little to criticise in Dr. Wylie's paper, as the operation was essentially the same as that which he had been performing for several years. Numerous as the operations were which had been devised for lacerated perineum, a perfect one had not been discovered, yet it was evident that equally good results could be obtained by several different methods of operating. The Baker Brown operation, that by the horseshoe line of denudation, and the use of quill-suture gave only superficial union, and therefore the results were worthless. The quill-suture, also, was like the old method of using boiling pitch to arrest hemorrhage after amputation, and was not entitled to any consideration at the present time. This operation, however, was still described in most text-books.

Dr. Hunter thought that there was a misconception on the part of many as to what the perineum really was, and that there was a tendency to ignore the perineal body, which was a most important part. Dr. Emmet, in his recent operation, had spoken of restoring the perineal support by narrowing the lower portion of the vagina, but Dr. Hunter thought that Dr. Emmet's operation really restored the perineal body, a part which had depth as well as length, and that in contracting or narrowing the lower portion of the vagina the perineal body was included in the operation. The ruptured perineal body could not be restored except by including within the operation the entire torn surface, which many times was extensive before rupture of the skin took place.

For many years Dr. Hunter had avoided denuding any tissue beyond the mucous membrane, and one special and great advantage of Dr. Emmet's operation was that it taught us what not to do. It mattered but little whether we called it vagina or perineum so long as the good results were obtained, and that was what Dr. Emmet's operation yielded.

With reference to material for sutures Dr. Hunter had used all kinds, and had obtained as good results with one as with another. Lately he had used catgut alone, and had never had better results.

One objection to Dr. Emmet's operation was that it removed rather more tissue than was necessary. Dr. Hunter's method of introducing the catgut sutures was to begin above and work forward and draw all the tissue up; with its use there had been no pain subsequently and no necessity for the use of the catheter.

Rupture through the sphincter ani had not been alluded to by the author of the paper, yet he would like to ask Dr. Wylie whether he had noticed cases of permanent cure of retroversion of the uterus by restoring the perineum. He had seen a good many cases, it did not always occur, in which the uterus, previously retroverted, remained in its normal position without the use of pessaries, after restoration of the perineum for complete laceration.

Dr. Wylie said that where the uterus was movable he had seen several such successes.

Dr. Hunter thought that if all the stitches in Dr. Wylie's operation were introduced from within outward, there would perhaps be a gain.

Dr. P. F. Mundé had listened with pleasure to Dr. Wylie's description of his new method of operating for incomplete laceration of the perineum. The first operation which he saw performed was for complete laceration, and by Simon. The operation for incomplete laceration was practically not performed at all upon the continent of Europe at that time, so far as he was aware. When he returned to this country he was surprised to see how successfully the operation for incomplete laceration of the perineum was being practised by Dr. Emmet and others at the Woman's Hospital. Dr. Mundé was familiar with the operations performed by Baker Brown, Dieffenbach, Langenbeck, and others, and was surprised to see how slight a modification of them resulted in restoring what seemed at least to be an almost perfect perineum.

Dr. Mundé adopted the new operation, and had been exceedingly well pleased with it. So far as he could ascertain with the finger, the groove on either side of the vagina which would have existed had not all the muscular fibres been included within the sutures, had been obliterated, thus showing that the muscles had been united. Out of sixty-five cases in private practice he had not had a failure, and the perineal body had been restored.

When rectocele was present the operation was more or less complicated and difficult. In the first case of that kind he encountered he found that when the sutures were passed as Emmet taught, the last suture to draw all the denuded portion up to the denuded mucous membrane in the centre, drew down the posterior vaginal wall; the result, however, was exceedingly satisfactory.

Subsequently he found that if the upper sutures, as one approaches the upper margin of the denudation, were introduced by inserting the straight needle directly backward down to the bottom of the pocket and then turning it abruptly—frequently breaking one or more needles—and bringing it out in the centre, and then passing it into the opposite side, deep, straight backward, and then directly outward, the deep muscles were included and satisfactory results were obtained.

Dr. Emmet in his new operation had spoken specially of taking up the fibres of the muscles, a point which Dr. Mundé had always believed in, and that without so much reference to the leaving of pockets.

Still further on in gynecological work, Dr. Mundé found that in certain cases there was a redundancy of tissue, and then he followed a method which he had seen Professor Simon employ, that of making a denudation of the posterior vaginal wall and passing the sutures directly

across and tying them in the vagina as the operation proceeded, to be followed by denudation of the perineum and insertion of the ordinary perineal sutures.

Concerning Emmet's new operation he had performed it, and it had been followed by gaping of the vulva, a criticism which he entered the first time he saw Dr. Emmet perform it. It was a good operation for rectocele, but, practically speaking, it did not restore the external portion of the perineum and left the vulva gaping.

Dr. Mundé thought that when Dr. Wylie spoke of making a square—

Dr. Wylie: A square when it is flattened out.

Dr. Mundé: That is the point exactly, for the old clover-leaf denudation when flattened out is nearly a square, and practically, therefore, it struck him that Dr. Wylie was following exactly the same plan, except that he was performing a rather easier operation than the clover-leaf, but by making a transverse denudation he did not go down into the pockets on either side. Dr. Mundé then referred to the difference in results obtained in private and hospital practice, and believed that the influence of good air, cleanliness, and disinfection were as important as in the larger operations, such as laparotomy. He had always used silver wire, but at the same time thought it did not make very much difference what material was employed for sutures, unless it was catgut, which he had not used much for fear that it would separate before union of the parts was sufficiently strong.

He would not say that he had seen retroversion cured by restoring the perineum, but he had seen patients who were able to get along without a pessary afterward. When, therefore, he found a combination of retroversion with complete laceration of the perineum, he had felt hopeful that, if he could keep the uterus in position for two or three months before the operation, the patient would be able to get along without a pessary when the perineum was restored.

Dr. Hunter thought that if there was one merit greater than another in Emmet's operation, it was that it restored the posterior vaginal commissure to its normal position almost exactly.

Dr. B. F. Dawson thought he might be excused for offering his views on the subject from the fact that he had simplified the operation for lacerated perineum to an extent that would permit many to be gynecologists, who would like to be, if they would listen for a few moments. The principle was to simply put things in the condition in which they were before the rupture took place. The duty of the operator was to *restore* the perineum and not to make a new artificial one.

When the œdematous swelling had subsided, the parts had restored themselves nearly to a natural condition. Even in the most fleshy women, and with the greatest amount of rupture *down to* the sphincter, there remained but a small bar of tissue deficient, and it was the duty of the operator simply to restore that deficiency. Why therefore denude to the distance of three inches when the laceration was only two inches in extent? After denudation, simple coaptation of the denuded surfaces was all that was required, and he wished to remonstrate against the multiplicity of sutures commonly employed. When he first began to operate he used, as he had been taught, six, eight, perhaps a dozen sutures, and he had skin and perineal abscesses, etc. During the last three years he had used only two sutures and had not seen a failure. He had kept his patients in bed not more than eight days, allowed them to walk about the room within ten days, and he had attributed his success to the simplicity of his operation. As Dr. Emmet had said, the denudation should be confined to that portion of the ostium vaginæ which will restore the normal perineum, and then passing only a sufficient number of sutures to hold the parts in position. Dr. Wylie, also, had shown the importance of bringing up the lateral tissues of the perineum, in order to secure the most satisfactory results.

The principle was to make the denudation only upon mucous membrane where the tear had taken place, and make it so as to be sure to reach the angles completely, and also as to enable the operator to take up the lateral tissue. Dr. Dawson introduces the sutures at some distance from the edge, not in the true skin at all, carrying the needle straight back until it reaches the angle of denudation, then rotating it and bringing it out through healthy tissue; then carrying it across, and carrying it through at a corresponding point on the opposite side.

Silver wire had served him well, and he had not seen any reason for changing what had done him good service. He regarded Dr. Emmet's operation as a nearly perfect operation. The only objection to it was that it was exceedingly difficult to perform; but, probably, if he was to go over his gynecological work again, Dr. Dawson would adopt it in preference to his own.

Dr. F. A. Castle referred to the influence exerted, by excessive abdominal tension, upon the lacerated perineum, and thought that if a little more attention was paid to this element of the trouble and the patient's intestines kept free from flatus, it would frequently make but little difference whether the woman had a perineum or not.

Dr. A. S. Hunter said that one of the important points in any method of treatment for restoration of a ruptured perineum was to secure the least amount of suffering possible during the time the wound was being healed, and in order to effect this the sutures should be inserted near to the line of union. He had performed Dr. Emmet's old operation in nineteen cases with nineteen successes, and most of the sutures measured from three-fourths to seven-eighths of an inch in diameter. The patients were all in private practice, and in good condition before the operation, but in every instance the patient suffered extreme pain. The sutures were inserted from one-fourth to one-third of an inch from the line of union, and opium was necessary to control the pain. In the twentieth case he had a very bad failure. He had seen Dr. Wylie perform his operation several times, and had been struck with the absence of any necessity for giving the patient opium to relieve pain, and the reason was because, probably, the sutures were not introduced through the skin. In his own cases also abscesses occurred along the line of some one of the sutures in about twenty-five per cent.

Dr. Cranmer would be pleased to learn something concerning the cause of laceration of perineum, as he had never had a case in his own practice of thirty years.

Dr. Boldt thought that the principal cause of abscesses along the line of the sutures was the fact that too many sutures were used, and also that they were twisted too tightly.

Dr. Castle thought that on account of the multiplicity of names which had been given to operations for lacerated perineum—"horseshoe denudation," "clover-leaf," etc.—Dr. Wylie's method might be called "Wylie's fig-leaf" operation.

Dr. Wylie closed the discussion and reviewed several points in the remarks which had been made by the gentlemen who had participated in the discussion.

BOARD OF STATE MEDICAL EXAMINERS.

Under the head of new business the Society unanimously adopted a resolution endorsing the bill recommended by the Medical Society of the State of New York in February last, making provisions for a Board of State Medical Examiners, and also recommended that the Committee on Legislation of the State Medical Society insist that the New York State Medical Association has no legal representation, and therefore is not entitled to any consideration in the bill.

Drs. William Oliver Moore and F. R. S. Drake were elected delegates to the Medical Society of the State of New York to fill vacancies.

The Society then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 25, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

(Continued from page 331.)

CONGENITAL CRANIO-TABES AND CHRONIC HYDROCEPHALUS.

DR. PRUDDEN also presented two specimens for which he was indebted to Dr. W. P. Northrup.

CASE I.—A feeble, ill-nourished child, twenty-eight days old, died with no head symptoms; nothing abnormal about the pupils. The thoracic and abdominal viscera were normal. There was spina bifida in a moderate degree. The forehead is moderately large and overhanging. The fontanelles and sutures were widely open and in the parietal bones are several small areas at which the bone is softened and perforated, the openings being covered by soft parts only—cranio-tabes. The brain-substance of the cerebrum is crowded against the skull by accumulated fluid, so as to form a shell of brain tissue on the average about one centimetre in thickness. The centre of the brain is occupied by a large bilobed cavity—the communicating dilated lateral ventricles. The basal ganglia are flattened and pressed downward against the base of the skull. In this case the space occupied by the dilated ventricles is about one-half that of the entire cerebral cavity. This, then, is an example of the class of cases of congenital hydrocephalus in which the child is born with the lesion in an advanced stage and terminating in an early death.

CASE II.—A female child, nine months old. Mother was healthy. The head of the child was rather large at birth. Since birth the child has vegetated well but has given no sign of intelligence except to exhibit signs of hunger. It cried as other children do, but most of the time lay in a stupid conditon. The head grew gradually larger from its birth and it seemed to grow more and more stupid, and for three or four days before death could not be made to take food, and so died.

At the autopsy the child was well nourished. The head was large, forehead overhanging, skull about eight inches in longest antero-posterior diameter. The thoracic and abdominal viscera were normal. The convolutions were flattened and there was but little fluid in or beneath the meninges. The lateral ventricles were widely dilated, measuring about three centimetres in lateral diameter and about the same vertically. The posterior cornua were widely but unequally dilated. The basal ganglia were considerably flattened. The third ventricle was cylindrically dilated and about one centimetre in transverse diameters. In this case the dilated ventricles occupy about one-fourth the entire cavity of the skull, the brain substance about the cavities being fairly well formed and its anatomical elements distinct.

This, then, is an example of that important class of cases in which the lesion exists at birth to a moderate degree and steadily progresses until the occurrence of death at an earlier or later period.

The specimens were good illustrations of three classes of cases: 1, Congenital hydrocephalus, in which the lesion is marked at birth and the child does not survive but a short time; 2, chronic hydrocephalus, in which the lesion is progressive after birth, the child living for some time; 3, hydrocephalus, in which the lesion is primary, in an adult; in this class of cases the primary cause is not known.

With reference to hardening the brain when in this condition, Dr. Prudden remarked that it was important to remove it under water, and to carry it in water to the place where the ventricles could be filled with the hardening fluid by means of a syringe as the fluid within the brain ran out, the brain always being kept in a fluid.

DR. JACOBI remarked that cranio-tabes occurred early, sometimes as early as the fourth or fifth month of life, but cases of congenital cranio-tabes were exceedingly rare. He had seen but a single case, and did not remember to have read of another.

DR. PRUDDEN remarked that the specimen he presented was the only one which he had seen.

DR. NORTHRUP said he had seen but this single specimen occurring in a child so young.

EPITHELIOMA THE RESULT OF CONTINUED IRRITATION OF A SIMPLE ULCER.

DR. GEO. F. SHRADY presented a specimen which might serve to illustrate the results of long-continued irritation of a simple ulcer. It was removed from a man forty-five years of age, who, one year ago last October, was burned upon the right side of the face and neck and chest. The wounds healed in about two or three months, with the exception of two small ones on the right side of the chest, which remained open up to the time of the operation. They were the source of more or less irritation until within the last four or five months, when they took on a new action. The small ulcers coalesced and formed one large one, granulations became proliferous in character, and when the patient presented himself a week ago at the St. Francis Hospital, Dr. Shrady found a large ulcerating surface, which he removed by simple operation. It was situated just below and to the right of the right nipple. The mass was apparently divided into two distinct portions, one a fungoid growth, and another which presented the appearance of epithelioma, and it had been proven to be such by a microscopic examination.

MULTIPLE FIBROID, HYDRO-SALPINX, AND MUCO-FIBROUS POLYPUS.

DR. H. J. BOLDT presented a specimen removed from the body of Mrs. B. S——; aged forty-one; born in Germany; married sixteen years; no children; no miscarriage; menstruation appeared at fourteen years. The duration of the present illness is about sixteen years, but its symptoms have increased much in severity during the past two years, the symptoms consisting of backache, cephalalgia, vertigo, metrorrhagia, extreme exhaustion, and pains in both inguinal regions. The amount of blood lost is exceedingly large, and occurs at irregular intervals. During the absence of the metrorrhagia there is a continual copious sero-bloody discharge; for the past two years the patient noticed a lump protruding into the vagina. She presented herself at my clinic on February 9, 1885, with the above history.

On digital examination, I find the protruding mass in the vagina to be a polypus with a spongy feeling to touch. The cul-de-sac of Douglas is filled out by a large mass which feels rather firm to the touch; the uterus itself does not seem to be enlarged upward, but to either side a hard mass is felt, which seems to be in connection with the uterus; the latter is slightly anteverted, due to the mass posteriorly. Inspection shows the polypus to be engorged with blood, the color being quite dark, and by the use of the uterine sound it is shown to be attached to the anterior surface in the body of the uterus. It was drawn down by a strong tenaculum and cut off as near as possible to its base with scissors, very little hemorrhage following.

The polypus consists of mucous and fibrous tissue. Her metrorrhagia ceased for a few days, but then began again. I sent her to the hospital for treatment and probable operation. On February 19th she was anæsthetized for the purpose of making a careful examination, it being a question as to the nature of the mass posteriorly. Unfortunately I ordered chloroform to start the anæsthesia, and then changed off to ether. She was not yet fully under the influence of the anæsthetic when lividity of the face was noticed, and the patient died of cardiac paralysis, although no pains were spared to resuscitate. Previous examination of the heart had not shown any pathological condition.

The cause of the cardiac paralysis I found by the au-

topsy to be due to a fatty degeneration of the muscular structure on the left side of the heart; the right side did not yet show such change.

The points to which I desire to call particular attention are, first, the danger of chloroform.

Second, when the diagnosis of hydrosalpinx has been made, and the sac is as large as in the present case, we should not hesitate to remove the disease by operation, as any slight cause, usually traumatic, may cause inflammation of the sac-walls; thus a "pyosalpinx" result, the sac is then very apt to burst at some point and cause fatal peritonitis.

Third, that the increase in the intensity of the patient's condition for the last two years was in all probability due to the polypus.

DR. AMIDON asked if the heart was examined before the administration of the anæsthetic.

DR. BOLDT replied that it was, but that there was no evidence of cardiac disease.

DR. AMIDON asked if it was not a rule commonly observed among obstetricians and gynecologists to use chloroform only in cases of labor when pain was actually present.

DR. NORTHRUP remarked that it was a common practice, even among those who were familiar with the dangerous effects of chloroform, to begin with the administration of chloroform and continue the anæsthesia with ether; and he would like to ask if that was not as dangerous as it was to use chloroform throughout; death occurring most frequently, in the use of chloroform, at the beginning of, or early in its inhalation.

THE PRESIDENT thought that the method mentioned by Dr. Northrup was even more dangerous than it would be to carry on the anæsthesia with chloroform alone. He thought also that the use of chloroform as a general anæsthetic should be condemned most fully in all cases, except possibly in children under twelve years of age.

DR. W. H. PORTER mentioned that Dr. W. T. Lusk had written a paper calling attention to the danger of using chloroform as an anæsthetic even in cases of labor, submitting the following propositions for argument and indorsement:

1. Deep anæsthesia, carried to the point of complete abolition of consciousness, in some cases weakens uterine action, and sometimes suspends it altogether.

2. Chloroform, even when given in the usual obstetric fashion, namely, in small doses, during the pains only, and after the commencement of the second stage, may in exceptional cases so far weaken uterine action as to create the necessity for resorting to ergot or forceps.

3. Patients in labor do not enjoy any absolute immunity from the pernicious effects of chloroform.

4. Chloroform should not be given in the third stage of labor. The relative safety of chloroform in parturition ceases with the birth of the child.

5. The more remote influence of large doses of chloroform during labor upon the puerperal state is a subject that calls for further investigation and inquiry.

He also cites a number of cases in which alarming symptoms occurred as the result of the chloroform, and several deaths directly attributable to the chloroform.

THE PRESIDENT remarked that he had heard of one fatal case from chloroform inhalation in obstetric practice.

DR. JACOBI asked what the condition of the heart was at the autopsy.

DR. BOLDT replied that it was the seat of a moderate amount of fatty degeneration, more particularly upon the left side, although the amount of degeneration was not very great. He further remarked that he had been accustomed to use chloroform as an anæsthetic for diagnostic purposes.

THE PRESIDENT thought it lamentable that physicians could not be convinced of the danger of using chloroform as an anæsthetic until they had been taught the lesson by the loss of a patient. He thought Dr. Boldt deserved credit for reporting his unfavorable experience, as in very many instances where such results had followed the use of chloroform nothing further was ever heard of the case, and doubtless death from chloroform had occurred in many instances which had never been reported.

HYDRO-SALPYNX—OPERATION—CURE.

DR. H. MARION SIMS presented a specimen with the following history: Mrs. S——, twenty-three years of age. Married two years. Never pregnant. Menses regular. Flow normal. Never had any pain with period until a year ago, when she got her feet wet and had "inflammation of the womb." Her menstruation thereafter was extremely painful, the pain preceding the flow by several days. Had a great deal of pain in small of back, which was almost constant, especially of late months. Had always been previously in most perfect health. Intercourse became more and more painful, until finally she could not submit to it at all. On examination I found the uterus in normal position, and directly back of it, in Douglas' cul-de-sac, I detected a growth which was so exquisitely sensitive to the touch that I could not make a thorough examination, so decided to give the patient some nitrous oxide gas in order to make a thorough examination. This was done on the following day, and the cyst easily mapped out and traced to its origin, the right tube. An operation was decided on, and was performed a few days afterward. The patient made a rapid recovery, and is now perfectly healthy. Menstruation normal and unaccompanied by any pain or discomfort.

Dr. Sims also presented

A SMALL OVARIAN TUMOR.

Mrs. B——, forty-one years of age. Married twenty years and mother of two children. Menstruation always regular, but had become more and more painful for two or three years past. She is a big, strong, healthy-looking woman, and had always enjoyed very good health. Two years ago she began to have severe pain over the left iliac region, with dragging pains across the back and down the limbs. She became very peevish and nervous, and her usual good health broke down considerably. I saw her first a year ago, and found her so sensitive to the touch about the uterus and ovaries, that I had to administer an anæsthetic in order to make a thorough examination. High up on the left side a small, round cyst was found, which I took to be either an ovarian cyst or one of hydro-salpynx. Operation was advised and performed shortly afterward. The right ovary being found in a cystic state was also removed. Patient made a good recovery, and is now enjoying excellent health.

DR. FRANK FERGUSON presented a specimen of

HYDRO-SALPYNX

removed from the body of a woman who died of pneumonia. There were old pelvic adhesions. There were three cysts which contained a clear fluid, in which cylindrical epithelium had been found in fairly large numbers.

CARCINOMA OF THE RIGHT OVARY.

DR. W. P. NORTHRUP presented a specimen with the following history: Patient was an unmarried female, aged sixty. She performed the various duties of cook, dressmaker, and child's nurse. Nothing was known of a tumor until two years before death, when, after overexciting herself she developed symptoms of peritonitis, and was attended by Dr. Walker, of this city, who made a diagnosis of tumor, and suspected its cancerous nature. A few months before death she became unable to work, and was admitted to an old ladies' home, where she died. She had become emaciated. Her weight in health had been over two hundred. On her face were two or three dark brown patches, which she designated "liver patches." Her conjunctivæ were somewhat jaundiced, her skin dirty yellow. In the hypogastrium and extending into both iliac regions was a large, symmetrical, smooth, tense, fluctuating tumor.

Uterus could be moved within moderate limits without moving the tumor. Patient died of exhaustion.

On autopsy a tumor weighing eight and a half pounds was found, apparently developed from the right ovary and adherent to the right broad ligament. It was attached by tender adhesions in several places, but these were easily stripped up with the thumb and finger, and it was necessary to cut only the broad ligament. The surface of the tumor was smooth and contained dilated veins. Its general shape was oval, and fitted closely down into the pelvis. On opening this fluctuating body dirty brown fluid escaped and allowed the bulk of the tumor to diminish fully one-half. On turning this sac wrong side out irregular-shaped nodules of a light color and rather yielding consistence, varying in size from an orange to a walnut, were found. These, on examination under the microscope, present the characteristics of carcinoma.

The tumor he thought to be of interest on account of its peculiar gross appearance.

Dr. Ferguson presented a specimen of

SPINDLE-CELLED SARCOMA OF THE BRAIN.

It was evident that the tumor began in the dura mater, and by pressure had displaced a considerable amount of the left hemisphere; it had also destroyed to a considerable extent the ganglia at the base of that side of the brain.

Dr. Ferguson also presented

A SARCOMATOUS TUMOR OF THE SPINAL CORD.

The cord itself had not as yet been examined microscopically. The condition of the other organs was that found in connection with crushing of the spinal cord, when the patient lives for six or eight months, namely, emaciation, contracture of muscles, cystitis, pyelitis, abscess of the kidneys, etc.

Dr. Amidon asked Dr. Ferguson whether his examination of the tumor of the cord had led him to infer the point of origin.

Dr. Ferguson replied that it seemed to arise from either the pia mater or immediately beneath the pia mater, because it apparently involved the cord from pressure rather than by originally taking origin in the structure of the cord. He was certain that it did not originate in the dura mater, as it was entirely unattached to the dura mater, although it was in contact with it.

Dr. Amidon remarked that the clinical history would point to the origin of the disease of the cord as pressure myelitis, as there were, first, symptoms of irritation; second, of compression; third, of destruction. The case seemed to be one of pure myelitis with ascending and descending degeneration.

Dr. Prudden asked if Dr. Ferguson regarded the tumor as sarcoma with secondary cystic formation.

Dr. Ferguson thought it might have been cystic from the first.

Dr. Jacobi asked Dr. Ferguson concerning the origin of the tumor of the brain.

Dr. Ferguson replied that it probably originated in the dura mater.

The Society then went into executive session.

Qualifications for Practice.—The conviction of Dr. Buchanan on a charge of conspiracy to issue bogus diplomas, suggests the inquiry as to whether it is more reprehensible to issue bogus diplomas to men who are not qualified to practice medicine than it is to issue genuine diplomas to men equally unqualified. There is reason to believe that a large percentage of the doctors sent out by colleges are no better qualified to practice medicine than Buchanan's bogus fellows. Buchanan, doubtless, deserves all the punishment he receives, if not more; but one cannot help thinking that there are a great many gold-rimmed college professors in different parts of the country who are just as bad.—*The Philadelphia Evening Item*, March 12, 1885.

PRACTITIONERS' SOCIETY OF THE CITY OF NEW YORK.

Stated Meeting, March 6, 1885.

A. B. Ball, M.D., President, in the Chair.

ABSCESS OF THE LIVER (?).

Dr. Beverley Robinson related the incomplete history of a case in which there had been a difference of opinion respecting diagnosis, with a view to calling out an expression of opinion of the members of the society. The patient was a man about thirty years of age, a clerk, who, three months ago, while in perfect health, went on a shooting trip, and while absent from the city was taken with symptoms of fever, and after a few weeks developed what his physician called typho-malarial fever. After a period of apparent convalescence, symptoms appeared which pointed apparently to suppuration of one of the internal viscera, and two prominent physicians expressed the opinion that there was abscess of the liver. Some days later the patient expectorated large quantities of pus, and this his physicians believed to come from an abscess of the liver, through the perforated diaphragm, or from an abscess of the lung due to embolism carried from an ulcer of the intestine. Dr. Robinson saw the patient about three weeks ago, when he made a very careful physical examination, and was unable to come to the belief that there was abscess of the liver. He found signs which to him were indicative of an old pleurisy, the inflammation having involved the lung and given rise to dilatation of the bronchial tubes, from which the profuse expectoration arose. He saw the patient again yesterday, and was informed that his physician had found a varying temperature, a part of the time it being nearly normal, again rising to 102° or to 103° F. The physical signs had not much changed, but within a week or ten days an abscess had developed in the left temporal region. The pus from this and the sputa had not been examined microscopically. There was now a point of tenderness over the inner aspect of the right thigh near the popliteal region, which it was feared would prove to be a commencing abscess. The question in Dr. Robinson's mind was, whether the pus which had been expectorated, and the abscess of the temporal region, had their origin in a pyæmic process starting from an old typhoid ulcer of the intestine, or whether the starting-point of sepsis was in a tubercular process in the lungs.

Dr. Peabody said, with reference to the possibility of typhoid ulcers giving rise to multiple abscess, that he had had two such cases, the patients, after becoming apparently convalescent, having a succession of chills and symptoms of pyæmia, dying with multiple abscess of the kidney.

Dr. Robinson asked whether the pus of a metastatic abscess showed characteristic appearances under the microscope.

Dr. Peabody replied, not necessarily. He further said, in reply to a question by Dr. Robinson, that secondary tubercular deposits might occur in any of the tissues of the body, but in some the occurrence was unusual.

OVARIAN TUMOR TWISTED FIVE TIMES UPON ITS PEDICLE.

Dr. J. B. Hunter said that, about six weeks ago, a woman came to him giving a history which made the diagnosis somewhat doubtful. According to the history, it was possible that she might be pregnant, but there was a very small enlargement which seemed not to be connected with the uterus. When she returned, at the end of a month, he was surprised to find a large ovarian tumor. She was not suffering much discomfort, but was advised to enter the hospital as soon as her circumstances would permit. Shortly after the patient entered the hospital her temperature rose, and, for two or three days, varied between 100° and 102°. Dr. Hunter supposed this to be due to inflammation in the ovarian tumor, and accordingly hastened with the proposed operation of laparotomy.

On Friday afternoon, when the operation was performed, the temperature in the axilla was 101.5°, the pulse 140. Her expression was anxious, and there was apparent commencing peritonitis. Cutting down upon the tumor, it was of a blue and congested appearance, and was found to be twisted five times upon its pedicle. The inner lining of the sac was separated from the outer, and the walls contained coagulated blood. There was a papillomatous growth attached to the larger tumor. There was no hemorrhage into the peritoneal cavity, nor evident signs of peritonitis. After removal of the tumor, the temperature fell, and all the unfavorable symptoms disappeared.

PLEURITIC FLUID RESEMBLING PUS, BUT CONTAINING NO PUS-CORPUSCLES.

DR. KINNICUTT related the case of a patient who entered his service at St. Luke's Hospital two weeks ago, with signs of pleuritic effusion. Two months ago the woman began to suffer from increasing dyspnœa and probable elevation of temperature. She gradually lost strength and flesh, and when she appeared for admission to the hospital the signs of distention of the pleural cavity with fluid were found, and verified by puncture with the hypodermic needle. The fluid was of a rich cream color, and of the consistency of diluted milk. Dr. Kinnicutt expected to find, on microscopic examination, serous fluid, with a moderate amount of pus, and was surprised to learn that no pus-corpuscles were present—only granular matter and cholesterin crystals. Paracentesis was performed, and fourteen or fifteen ounces of a like fluid was withdrawn, which also, under the microscope, was free of pus-corpuscles. Dyspnœa was relieved by the operation; the patient was rendered comfortable, and had no fever. The question arose as to what was the nature of the fluid withdrawn from the chest. It resembled very much the fluid of a cold abscess, but he had never before seen such an effusion into the pleural cavity. The patient was not suffering from any bone disease.

DR. PEABODY thought that, whatever name might be given to the collection of fluid, it was pus which had become broken down and was ready for absorption. After a while it probably would have become absorbed, leaving a caseous mass. But it was unusual to have so large a quantity of pus in the pleural cavity undergoing such a process. The reason why we failed to find pus in abscess of the liver, was that the pus had become broken down.

DR. V. P. GIBNEY was reminded by the case of Dr. Kinnicutt of that of a girl of eight or ten years of age, who came to him some years ago with supposed abscess of the liver, the enlargement extending from the region of the liver transversely across the abdomen to the left iliac region. The patient was also seen by Drs. Thomas, Walker, and Ripley, the latter two gentlemen aspirating and drawing off a large quantity of fluid, which had the appearance of milk and contained cholesterin crystals with a few pus-cells. If he remembered correctly, Dr. Thomas said the fluid was not uncommonly seen in ovarian tumors; at all events it was not regarded as a very anomalous kind of fluid.

DR. WARD said it was not unusual for dermoid cysts to contain fluid like that described by Dr. Kinnicutt, and that such a cyst might develop in that locality, although it seldom did so.

DR. PEABODY then read a paper on

UNUSUAL CASES OF APOPLEXY, WITH ANATOMICAL DEMONSTRATIONS.

DR. MCBRIDE had been very much interested in the histories of the cases reported by Dr. Peabody, as he had recently had occasion to look up the literature of the subject of cerebral hemorrhage in the young. He had been somewhat surprised to find that in the majority of cases of supposed cerebral hemorrhage in the young subject, aside from meningeal hemorrhage, there was heart disease, and with the heart disease was almost invariably associated aneurisms in the cerebral vessels. A number of the cases were reported in the transactions of the Pathological Society of London. In one case the patient was but thirteen years old, in another nine, and the ages ranged all the way up to twenty-five years.

In one of the cases reported by Dr. Peabody, the young man's rapid growth must have been accompanied by anæmia, and in connection with malnutrition of the vascular system we were likely to have dilatation of the left ventricle. The writer on diseases of the circulatory system in "Ziemssen's Encyclopedia," spoke of the frequency of the presence of anæmia and endarteritis obliterans in cases of hemorrhage. Dr. McBride inquired of Dr. Peabody whether a thickening of the walls of the blood-vessels was recognized during the life of the patient.

DR. PEABODY replied that the patient was in apparent good health, and his blood-vessels were not examined before death. Recklinghausen, in his recent work on "General Diseases of the Circulatory Apparatus," stated that he had never seen a case of apoplexy in the young subject unaccompanied by Bright's disease of the kidney. In the second of the two cases reported by Dr. Peabody there was no disease of the kidneys. In the other case there was Bright's disease of one organ, with compensatory hypertrophy of the other. Why the disease should have been limited to one kidney Dr. Peabody was unable to explain. There was no local cause for it.

DR. KINNICUTT inquired as to the nature of the varicosity of the cerebral vessels spoken of in the history.

DR. PEABODY said there was simply a bulging or enlargement of the calibre of the vessels without any change in their walls. He had examined the brain very carefully for several hours after maceration, but was unable to detect any aneurism.

DR. KINNICUTT inquired whether recent investigations went to show that simple arterial tension, without disease of the blood-vessels, was sufficient to cause rupture of the vessels. In an article which he had read some years ago, the author stated that it was considered that arterial tension alone, without disease of the blood-vessels, could not cause rupture.

DR. PEABODY replied that as good authority as Recklinghausen claimed that rupture of the vessels might occur without disease, basing his opinion upon cases in which he was unable to find any pathological change at the seat of rupture.

THE PRESIDENT remarked that the statement of Stroud (?), with regard to the death of Christ being due to rupture of the heart, had been rejected by some, because it was claimed that the heart could not be ruptured except in disease. In the light of Recklinghausen's observations, however, Stroud's view could be accepted without regarding Christ as imperfect physically.

DR. DANA doubted whether it was so rare to meet with cases of cerebral hemorrhage in children, not of meningeal origin. He had met with two or three cases, apparently of the kind referred to by Dr. Peabody. Within the last year a man, twenty years of age, had come under his observation for supposed post-hemiplegic chorea, following cerebral hemorrhage, which occurred several years ago. His symptoms had been those of cerebral hemorrhage, not of meningeal origin. He now had under treatment a boy with epilepsy, who, when sixteen years of age, had presumable cerebral hemorrhage, with temporary loss of power of the right side. He also had notes of two or three other similar cases, none of the patients dying. According to his experience, young people were not so likely as old people to have a recurrence of the hemorrhage.

DR. MCBRIDE thought it impossible to make a positive diagnosis of cerebral hemorrhage without knowing the early temperature.

DR. DANA did not think the temperature record would

settle the question of diagnosis. It was extremely varying in different cases. He had seen it in one case rise only on the paralyzed side; in another it steadily rose to 105° F., and the patient died; in another it rose one or two degrees, and entirely ceased to rise in the course of ten days.

Dr. Gibney inquired whether Dr. Dana referred to what was known as infantile hemiplegia.

Dr. Dana replied that he did not; in such cases he supposed the hemiplegia due probably to meningeal hemorrhage, and not to apoplexy; but in older children, from eight to sixteen years of age, he thought he could fairly say whether or not there was cerebral hemorrhage.

Dr. Peabody then read a paper on poisoning from bichloride of mercury dressings.

Dr. Peabody said that since writing the histories of the foregoing cases, he recalled two or three others in which symptoms of poisoning by the use of bichloride of mercury as a dressing developed. The cases which he had reported were obtained from the records of a single hospital, and probably did not include all which occurred there. They consisted of six deaths after the use of the bichloride, and a number of cases with peculiar symptoms in which death did not take place. The symptoms were characteristic, and consisted of tenesmus, pain, frequent bloody stools, and obstinacy to all ordinary treatment. The writer in "Virchow's Archives," referred to, described the symptoms very minutely, and they tallied exactly with those observed by Dr. Peabody. At the post-mortem he found a great many ulcers affecting the large intestine, and very frequently also the small intestine, with or without membranous deposits.

Dr. McBride asked whether the urine gave any indications of the amount of the bichloride being absorbed by the system.

Dr. Peabody replied that he did not know that any examination of the urine had been made with a view to determining this question in the cases reported by him. Fränkel stated that the symptoms mentioned were present without any evidences to be found in the urine, so that the appearance of the urine could not be taken as a warning that there was mercurial poisoning any more than could be salivation.

Dr. Kinnicutt asked Dr. Bull if it was necessary to employ the bichloride in so strong solution as mentioned in the histories of the cases, in order to have complete antisepsis.

Dr. Bull replied that it was not always necessary to employ a solution of the strength of 1 to 1,000. It had been found that 1 to 2,000 or 1 to 5,000 would do. There was one point in the paper which he could not but criticise, inasmuch as the evidence was drawn from post-mortem observations. In a number of the cases the patients were suffering from old sinuses due to diseased bones, and consequently some of the symptoms attributed to mercurial poisoning might perhaps be interpreted in a different way. We all knew that in many cases of suppurating joints and bones, there were also tubercular deposits in the intestine, and these may have had something to do with causing diarrhœa and dysenteric discharges. Of course this would not explain the presence of diphtheritic deposits. He certainly had not seen any case of death in which these intestinal symptoms were present, and in which bichloride of mercury had been used, but he must say that he had been a little more conservative in the use of the disinfectant than some other surgeons. He had employed carbolic acid a good deal where continued irrigation was required. Then he dressed wounds mostly with iodoform, and rather encouraged the house staff to abstain from much washing of wounds with the bichloride solution unless they were the seat of mal-odor, etc. He could not help thinking that a solution of 1 to 5,000 would often answer just as good a purpose as one of 1 to 1,000.

Dr. Sexton said he had been informed that some physicians employed a twentieth of a grain of corrosive sublimate two or three times a day for the cure of dysentery. He thought that this was a larger amount of the salt than would be absorbed from a wound washed with a solution of 1 to 1,000, which it was claimed gave rise to dysentery. This might be evidence in favor of one of the claims of homœopathy, of the difference in result from the administration of a large and a small dose of the same medicine.

Dr. Dana remarked that one recent writer in Volkmann's *Sammlungen*, reached the conclusion that bichloride of mercury was an excellent surgical dressing if properly used; while another, in considering its use in obstetrics, reached the conclusion that it should not be employed at all; that it was a very pernicious agent.

Dr. Robinson had seen the bichloride used in syphilitic cases very extensively, and had not known of any cases of dysentery arise from it.

The President thought it was not very unusual for a patient to have a diarrhœa due to the administration of bichloride of mercury by the mouth. Moreover, might not the symptoms differ according to the way in which the poison found its way into the system? He had known, for instance, an infinitesimal quantity of carbolic acid to produce well marked carbolic acid poisoning. In one case it arose from a dressing with the faintest odor of carbolic acid, applied over a drainage-tube introduced into the chest in a case of empyema. The amount of carbolic acid absorbed, however, was sufficient to produce perfectly black urine. Again, we could not be sure that all the bichloride of mercury taken into the stomach was absorbed.

Dr. Peabody thought that the albumen of the food, coming in contact with the drug, might prevent its absorption.

Dr. Gibney said in support of this theory, that it was a common practice at the Hospital for the Ruptured and Crippled, to give children, year in and year out, a mixture containing bichloride of mercury and cinchona bark, known as the brown mixture, each dose, of which two or three were taken daily, containing one twenty-fourth of a grain of corrosive sublimate.

Dr. Dana estimated that there were about fifteen grains of the bichloride in a quart of a solution of one to one thousand, which offered a fair chance for the absorption of an excessive amount.

The Spelling of Medical Men.—Dr. N. O. D. Parks, writes with much feeling, and unexceptional orthography, upon this subject. He says: "Commenting on the execrable spelling which too frequently disgraces the profession in the preparation of physicians' certificates when brought under public notice in courts of justice, you wisely remark that, 'attention to the small matter of spelling . . . will frequently save the profession from public humiliation.' It is plain to the most unobservant that it is impossible for a man to pay attention to spelling if he does not know how to spell. The true and only remedy is to apply the pruning-knife with relentless hand to the countless diploma mills which spread their noxious miasm throughout the length and breadth of the land, and to make it a *sine qua non* that every student, before entering on his purely professional studies, shall give evidence of his having received such a liberal education as will qualify him to associate with gentlemen of other learned professions."

Cocaine in the Cure of the Opium Habit.—Dr. A. P. Meylert, of this city, writes that cocaine in the treatment of the opium habit has quite disappointed him. "I have found it of comparatively little value during the period antecedent to discontinuance of morphia. I have had no reason to change the opinion expressed to the County Medical Society, and published in their proceedings December 27, 1884, in The Medical Record." Dr. William Oliver Moore writes that an article bearing on this subject will be found in *Centralblatt für Therap.* August, 1884.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ANNUAL COURSES OF LECTURES AT THE COLLEGE OF PHYSICIANS—DR. OSLER'S GULSTONIAN LECTURES—PROPOSED AMALGAMATION OF THE BRITISH AND INDIAN MEDICAL SERVICES—THE INDIAN MEDICAL SERVICE—THE SOUDAN EXPEDITION.

LONDON, March 7, 1885.

THE annual courses of lectures at the College of Physicians are now in progress. These are three in number, viz., Gulstonian, Croonian, and Lumleian, so named after their respective founders, who severally bequeathed to the college a sum of money to endow the lectureships. The President has the privilege of appointing the lecturers.

The Gulstonian Lectures for the present year have just concluded. The course consists of three lectures, and a condition of the endowment is that one of the junior fellows be appointed as Lecturer. A special interest attaches to the course just given from the fact of a Philadelphia physician, Dr. William Osler, being the lecturer. Dr. Osler took for his subject that rare affection known as ulcerative, or, as he preferred to call it, malignant endocarditis. Although cases of this disease are from time to time reported in the medical journals, no very complete account of it has yet got into our text-books on medicine. Even "Quain's Dictionary" contains but a very brief account of the affection. Its importance would lead us to expect a detailed account in such a work as "Quain," and, considering that no fewer than seven columns of small type are devoted to so specialized a subject as the Morbid Histology of Insanity, the omission is the more remarkable.

Dr. Osler gave in his lectures a very full and complete account of our present knowledge of the subject, and one, too, which his hearers could scarcely fail to notice was quite up to date. He justified his selection of the term "malignant" to describe this form of endocarditis by remarking that there were cases in which "ulceration" does not occur. It is, of course, impossible for me to epitomize within a few sentences the lengthy account of the disease given by Dr. Osler, bristling as it did with innumerable references to authorities, American and European. Those who heard his three lectures could scarcely fail to form from them a very clear idea of the disease, whatever they might have had before. I need hardly reproduce Dr. Osler's own views for your readers. As an American authority, his opinions are doubtless already familiar to them.

The proposal to amalgamate the British and Indian medical services is again on the carpet. Strange as it may seem, we have in India two distinct medical services working side by side. One of these consists of those officers of the British Army who are for the time being serving with British regiments in India, and who are under the control of the Director-General of the British Medical Service—he being stationed in London. The other is the "Indian Medical Service," which comprises two sections, viz.: "military" and "civil." The "military" includes all medical officers of the Indian Army: the "civil" those who hold dispensary and other government appointments in India. Both of these branches are under the control of the Indian Government; but, anomalous as it may seem, the competitive examinations for admission to the Indian Medical Service are held only in London. The natives of India are not debarred from competing, but, of course, this arrangement practically excludes a large number of them. To complete the anomaly, if they compete at all, they have to face an examination conducted wholly in English. It is, therefore, not surprising that they should, as a rule, be in a minority in the pass-lists.

As we are at war, such telegrams as the following occasionally come to hand: "Surgeon Turner died to-day." Then, again, correspondents from Egypt tell us how the doctors "shared with a courage and zeal beyond all praise in all the dangers of the day." Nevertheless, carpet officers at home still pretend to look down upon "non-combatants" and even officials still draw a red-tape line between combatant and non-combatant officers. Those who have been wounded know how to value the services of the surgeons, often rendered under fire.

Already several deaths are reported from enteric fever and from dysentery, and as our army is to remain in Egypt through the summer, not a few of us are fearing that disease will destroy more than the sword. All reasonable precautions seem to be taken, and never was an expedition better supplied with medical comforts. A telegraph ship has been chartered and fitted up with the largest condensing apparatus ever constructed. The enormous cable-tanks are to be utilized to contain the water as it is condensed, and are said to have a capacity of 750 tons of water. The sea-water will be collected off Suakim and condensed at the rate of 64,000 gallons a day, and from the tanks it will be conveyed to the shore in boats.

THE UNIVERSITY OF VERMONT AND MEDICAL DEGREES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of February 14th you quote from *The Hospital Gazette and Students' Journal*, that "the authorities of the University of Vermont, U. S., have announced that they will grant the M.D. degree to British registered medical practitioners of good standing, who pass a satisfactory examination in medicine, surgery and midwifery. No residence is required, and the examination can be passed in three days."

I would respectfully call your attention to what the University of Vermont *does* announce, and thus correct an impression which might be formed by your readers by the perusal of the above statement.

We have, for many years, offered to graduates of other regular colleges the privilege of being examined in practice, surgery and obstetrics, and, if found qualified, of having the degree of M.D. conferred upon them by our institution. So far as I know, this is the practice of all university medical colleges in this country; some require an examination in all the branches, but none refusing to grant a diploma to graduates of other accredited colleges, who apply for the honor and satisfactorily fulfil the requirements of the case. The University of Vermont has included registered practitioners of England in the exercise of this privilege, and thus a physician in good standing, who has the title of F.R.C.S. or M.R.C.S., can proceed to the degree of M.D. at this institution in the same manner as other regular graduates residing in this country. We require the candidate to appear in person, present a genuine diploma, prove his identity, present a certificate of character and of professional standing, and undergo a thorough examination in practice, surgery, and obstetrics. We announce that the examination can be passed in three days. In like manner a physician in good standing in this country can pass the examination for the degree of F.R.C.S. Eng. in twelve hours.

The fee which we exact is a nominal one, and designed simply to cover expenses.

We consider it rather an honor than otherwise to have this class of medical gentlemen added to our alumni, and we observe every possible precaution to prevent any who could affect the reputation or good name of the institution from obtaining the degree.

I am yours respectfully,

A. P. GRINNELL, M.D.,

Dean of the Medical Department, University of Vermont.

BURLINGTON, VT., February, 23, 1885.

ANTISEPSIS AND THE DANGERS OF BOVINE VACCINATION.

To the Editor of The Medical Record.

Sir: While the experience of Dr. Doughty with bovine virus (Record, February 21st) is probably not very rare, I believe it is entirely avoidable. Septic poisoning is impossible without the introduction into the circulation of micro-organisms or the products of their growth. With our present knowledge of these organisms, and the efficient means at our command for their destruction, the danger of this accident can be reduced to the vanishing-point.

The following queries suggest themselves: Was the surgical cleanliness of the skin at the point of inoculation made reasonably certain? Was the instrument with which scarification was practised cleansed *immediately* before using? Were the hands of the operator surgically clean? Was the resulting wound properly protected against the entrance of septic matter?

If these precautions were taken the responsibility for sepsis must rest with the party who furnished the virus. If not, it is impossible to locate it. It is no sufficient answer to say that these details are commonly ignored, that the operation is daily performed with impunity in utter disregard of the principles of aseptic surgery. If security against septic infection is desired, its price must be paid. The trouble involved will not, let us hope, be seriously weighed against the welfare of our patients. It is not possible in practice always to say whether septic matter is present or not. The only safe plan is to assume its presence whenever it is probable that, *if present*, it will enter the circulation and work fatal mischief. The suggestions of experimental biology already carried out with such brilliant results in clinical surgery render its complete destruction an easy matter. So easy and certain are these methods that Mr. Lawson Tait, the gospel of whose daring surgical practice is CLEANLINESS, has been led to declare "that any man who deliberately performs an operation under circumstances from which his patient acquires fatal blood-poisoning ought to be the subject of a criminal indictment." However this may be, the time is certainly not far distant when a case of septic infection will be just as properly a subject of judicial inquiry as a deformity from a fracture or dislocation.

It happened to me once, a few years ago, to witness a comparatively large number of cases in private practice where disastrous results had followed vaccination. They were, for the most part, phlegmonous inflammations, some of which threatened both life and limb. Some physicians seemed much more unfortunate than others. One gentleman, *whose practice was largely surgical*, had the most appalling consequences. Others, although performing numerous vaccinations, saw no unpleasant effects. Yet all, so far as I know, received their virus from the same vaccine farm. Of course, it was bovine. But if this fact had any relation whatever to the "unexpected which happened," it is at least strange that the cases were not somewhat more evenly distributed.

In the cases reported by Dr. D. it would be interesting to know which of the two children was vaccinated first. If a contaminated lancet had been used, it is entirely possible that the septic matter had been in whole, or in part, removed from the point by the first scarification, thus rendering the escape of the second child more probable.

Modern science, and especially practical biology, has rendered it possible for the physician, who is not "too busy," to be conscientious and careful to so perform a vaccination as absolutely to secure the patient against septic infection, unless the poison is contained in the virus. For this the practising physician cannot be rightly held responsible. The task of securing medical expert service, and furnishing a pure lymph, presents no difficulties which are insurmountable, and rests with the proprietor of the vaccine farm.

G. W. McCaskey, A.M., M.D.

History of Previous Epidemics of Cholera in the United States.—Dr. Rauch, in an address delivered before the American Public Health Association, gives the following account of previous cholera epidemics in this country: "The epidemic of 1832 is attributed to the ship Carrick, which arrived at the Grosse Isle quarantine station in the St. Lawrence River on June 3, 1832. But six days before that, the ship Elizabeth had arrived with 200 immigrants on board, having had 20 cholera deaths during the voyage. Fourteen days before the Elizabeth the Robert had arrived, with 10 cholera deaths; and sixteen days before the Robert—that is, on April 28th, thirty-six days before the arrival of the Carrick — the ship Constantia arrived, having had 29 cholera deaths during the voyage. These are all known to have been cholera-infected vessels, and their hundreds of passengers were known to be cholera-carriers; but these passengers are only a small fraction of the 30,000 immigrants who arrived in the St. Lawrence during the spring and early summer of 1832, from the same infected localities, and sailing from the same infected ports as the passengers of the Constantia, the Robert, the Elizabeth, and the Carrick. And yet they failed to develop a single case in Canada or elsewhere until June 8th. The introduction of the disease into New York is attributed to Canada; but the same class of immigrants from the same localities in Europe, were arriving in New York during the spring of 1832, as those in the St. Lawrence. And yet no case of disease occurred in the city or vicinity until June 13th.

"In 1848, the noted cases of the New York and the Swanton occurred—the former carrying cholera into New York, the latter into New Orleans; and to them is attributed the epidemic which, in the two succeeding years, spread from the Atlantic to the Pacific and from Canada to the Gulf. But the importation by the New York, though causing 50 deaths at quarantine, resulted in only 2 cases in New York city, and it was not for months afterward—not until May 11, 1849, and after the arrival of several other ships with cholera on board, that the first case appeared in the city, and the disease began to spread from that point. On the other hand, immigration from cholera-infected districts of Europe into New Orleans had been continuous for months before the arrival of the Swanton—the two vessels immediately preceding her, viz., the Gutenburg and the Callao, having lost 25 passengers from cholera.

"From this time until the close of what is generally known as the epidemic of 1854, but which was really only a continuation of the epidemic of 1848–49, there were continual importations of cholera carriers either in the persons of those who had been exposed, or in cholera-infected articles; in November, 1853, for example, no less than 28 vessels, on which 1,141 persons had died of cholera, arrived at the port of New York alone.

"The case of the Atalanta, in 1865, has already been

noted; but it should be further observed that there were three other arrivals from Havre soon after, and on the last two of these there were deaths from cholera during the voyage; but the disease got no nearer the city than Ward's Island, and by December 20th, had entirely ceased. In 1866, cholera was carried into Halifax by the steamer England, which vessel afterward proceeded to New York, where, on April 20th, she landed 891 passengers and 116 officers and men, having lost 316 by cholera. There were eight cases and five deaths among those who had to do with the vessel at Halifax, but no other extension of the disease, and none in New York. Two days prior to the arrival of the England, the Virginia had arrived at New York quarantine, having had 116 deaths on the voyage; and before the first death of the epidemic of 1866 had occurred, namely, May 2d, there had been nearly three thousand arrivals in New York of individuals 'who had been directly exposed to the infection of cholera at Liverpool, on shipboard, and at quarantine.' Notwithstanding this, so slowly does cholera spread, except under favorable conditions, that there had been only 21 deaths from the disease up to July 8th; and it was not until the first week in July that the disease appeared in Brooklyn, although there were frequent arrivals of cholera vessels during all this time.

"The epidemic of 1873 was preceded—*fourteen months before the first case of the epidemic occurred*—by the arrival of the Franklyn at Halifax, November 6, 1871, in distress, having lost 28 of her steerage passengers by cholera. Five cases, with three deaths, resulted from her on shore, but the disease did not spread, either in Halifax or vicinity. The vessel proceeded to New York, where she arrived November 12, 1871, having lost 11 more of her passengers, and having 72 cases then on board. But no epidemic followed. During 1872 there were numerous arrivals from cholera-infected ports, and the disease appeared on the island of Cuba and in Jamaica in the autumn of that year. During December, 1872, and January, 1873, there arrived at New Orleans a total of nearly two thousand immigrants from cholera-infected districts of Europe. And yet it was not until February 9, 1873, that the initial case of this epidemic occurred in the city of New Orleans."

Chloride of Ammonia is regarded by some as the most efficient remedy in sclerosis of the connective tissue, even of the neuralgias, and they claim, if it is used as freely as the iodide and bromide of potash have been in other disorders, its good effects will become manifest. Some enthusiasts say it is not only useful in cirrhosis of the liver and fibroid phthisis, but in all cirrhotic affections of the connective tissue of all the viscera, including those of the brain and spinal cord, to say nothing about strictures of the urethra and other parts. In chronic bronchitis it has obtained a reputation, not only when the sputa is thick and tough, but also when the connective tissue is swollen, thickened, and hardened. It relieves jaundice from occlusion of the biliary ducts by thickened mucus, and the neuralgias which arise from congestion, inflammation, and thickening of the nerve-sheaths. However all this may be, when rubbed on warts three or four times a day it removes them rapidly. Missisquoi water was once recommended for cancer, and lastly for mosquito bites. It is to be hoped that the muriate of ammonia will maintain its almost well-earned reputation against cirrhotic and sclerotic affections.

Spiræa Ulmaria (?) in Enlargement of the Prostate.—Dr. C. G. Brooks, of East Boston, writes: "The Record of July 5th contained an item on the use of 'Spiræa Ulmaria in Enlarged Prostate.' This item has been going the rounds of the medical press for nearly two and a half years; it is an abstract from an article by Dr. J. Baugh, of Hamilton, Ontario, published in *The Canada Lancet*, August, 1882. Dr. Baugh writes, after detailing the symptoms of a patient suffering from retention of urine, caused by an enlarged prostate: 'I tried my former method of treatment, but it failed. I also failed to use the catheter. Matters were becoming alarming, and I was about to send for professional assistance, when it came from another source, viz., an old woman. She volunteered the information that the patient wanted a dose of Queen of the Meadow (the common name for Spiræa ulmaria), and that if he got it, it would cure him in quick time. She said some could be procured in a few minutes. I asked her to get it. It was brought, an infusion was made, and a half pint given to the patient, and in fifteen minutes he desired to micturate, and emptied his bladder without difficulty. Since that, the patient has needed no medical or surgical aid to rid him of his old enemy. If he gets on a spree and his old trouble threatens him, he takes Queen of the Meadow tea and rejoices in being saved.' My object in sending to you this long extract is the desire to learn, if possible, what is the proper botanical name of the plant which proved so signally beneficial in Dr. Baugh's case. I have strong reasons for thinking that Eupatorium purpureum was used, instead of Spiræa ulmaria. I wrote to Dr. Baugh, a year ago, asking him whether he used the plant which bears a pinkish white flower (Spiræa ulmaria), or a purple blossom (Eupatorium purpureum), but received no reply. If you agree with me that the question is worth settling, I should be pleased to have the assistance of The Record in so doing."

Aconite Poisoning.—Dr. H. Speier, of Jordan, Minn., writes us that "the case of poisoning by aconite, with its miraculous escape, referred to on page 195 of The Medical Record, and which was widely circulated by the daily papers of St. Paul and Minneapolis, is generally considered to have been a clever advertising dodge by a 'specialist,' who is now under bonds for practising without a State license. A case of poisoning by aconite occurred in my practice about a year ago. A woman, waiting in a drug store for her physician, helped herself to a draught out of the aconite bottle standing on the counter, thinking it to be whiskey. She took about half an ounce. By an emetic, recumbent position, and stimulation I saved her."

Conservative Surgery.—Dr. J. M. Perkins, of Grove Spring, Mo., sends us an interesting report of a case illustrating the possibilities of conservative minor surgery. A boy, aged seven, was riding on a wheat-driller when the second phalanx of his index-finger caught in the cogs and was completely extirpated. Dr. Perkins removed the lacerated tissue, adjusted the first and third phalanges together, dressed the finger with tobacco leaves, and it healed rapidly, giving him a good finger.

The Spray in Ovariotomy.—Dr. John Homans, of Boston, writes: "The following is an extract from a recent work by Dr. Emmet ('Emmet's Principles and Practice of Gynecology,' page 715): 'In this country I do not know of any prominent operator who now employs the carbolic-acid spray.' This statement implies that the writer is not persuaded of the value of spray in ovariotomy. My own experience has led me to an opposite opinion. Indeed, I should not like to do a laparotomy for any purpose without antiseptic spray. I have been led to this conclusion by the results of one hundred and eighty-three cases of removal of cystic ovaries, of which I have lost only twenty-one—but more especially by the result of the last one hundred of these cases only ten of which were fatal, while thirty-eight were consecutively successful. I feel that to omit the antiseptic spray would be to deprive the patient of one of the ready and efficient elements of success."

Acidum Sulphurosum.—Most of its uses are based upon its power of killing germs and arresting fermentation and putrefaction. In pyrosis with yeasty vomiting and development of sarcini; in parasitic skin diseases, such as tinea, ringworm, etc., it should be applied locally, diluted with water and a little glycerine.

A CONTRIBUTION TO THE STUDY OF SEVERAL UNUSUAL FORMS OF SENSORY EPILEPSY WHICH ARE PROBABLY DEPENDENT UPON LESIONS OF THE OCCIPITAL CORTEX.

By ALLAN McLANE HAMILTON, M.D.,

NEW YORK.

I.

Epilepsies in which hemianopsia, hemicrania, and speech disturbances were associated with ill-defined fits.—Several years ago I directed attention to a form of epilepsy in which sensory disorders predominated, and referred to the examples collected by Sommers and others. These examples were characterized by predominant hallucinations or protracted special sense auræ, and might be included under the head of Lyner's third group of *Gesichtshallucinationen*.[1] Since the publication of this article,[2] I have met with other cases which convince me beyond doubt that there is a true sensory epilepsy which is as important, in its way, as the well-known variety described by Hughlings-Jackson, in which definite motor disturbances mark the disturbance of the para-Rolandic cortex; and such examples are of more than usual interest just now in connection with the late researches of Münk, Wernicke, Krause, Starr, and D. J. Hamilton.

Clinically, I see no reason why they should be looked upon as instances of classical epilepsy with unusual sense auræ, for there is a well-marked and defined grouping of the associated symptoms; and the motor expressions are secondary in importance. There are two cases in particular that bear so close a resemblance to each other that I shall detail them and afterward refer to one or two others reported by continental observers.

CASE. I. *Sudden hemiopia; supra-orbital neuralgia; unilateral anæsthesia of extremities, tongue, and gums; temporary speech disturbance; loss of consciousness.*—J. B——, a bright boy, aged sixteen, was sent to me by Dr. J. H. Browne in April, 1883. He comes of nervous stock, his mother being subject to epilepsy, and his father is an eccentric man who manifests his mental peculiarities chiefly in a morbid restlessness and irascibility. There is a brother who is healthy. The attention of the parents was first called to the boy's condition by his recital of a sudden attack which occurred during the summer of 1882. While rowing upon a river he suddenly and completely lost the visual use of the right eye, so that in looking at a number of ducks swimming near his boat, he failed to perceive those upon one side of the flock. This condition lasted for twenty minutes, and after a brief and severe pain over the right eye, he became unconscious, the unconsciousness being preceded by a tingling and numbness of the hand, forearm, arm, and left side of the tongue. He has subsequently had eight or ten of these attacks, of which the following is an example:

Usually without any bad feelings, physical or mental, he, while engaged in any duty, or at any time, suffers a sudden unilateral blindness. This is never gradual, and not like the form of amblyopia in which the visual field is gradually reduced. There is some hemichromatopsia. It would seem as if the retinal anæsthesia was unequal, for while usually the loss is complete and universal, it sometimes happens that there is only a limited loss. Upon one occasion, while reading, he suddenly lost the printed matter of the right lower half of the page below a diagonal line extending from the right upper corner to the left lower corner. There is never diplopia. This deprivation lasts anywhere from ten to twenty minutes; meanwhile a distal anæsthesia, coming very gradually, involves, at first, the fingers of the opposite hand and successively extends to the forearm, arm, and other parts, as I have already mentioned. There seems to be analgesia, as well as anæsthesia, for a pin may be run into the muscles without producing pain, and upon one occasion the gum was freely pricked without any discomfort to the patient. It invariably happened that the cutaneous sensory trouble occurred upon the side opposite to the hemianopsia and neuralgia, and in the greater number of instances, the left side was that affected. The third stage of the attack consists in migrainous headache of a very severe kind, and which sometimes lasts for an hour or more. There is a subjective feeling as if the eye was pushed forward. This disappears with nausea and relaxation. More often he loses consciousness when the anæsthesia reaches its limit, which seems to be the extension of the anæsthesia to the gums. Occasionally there are slight convulsive movements upon the anæsthetic side. While the attacks involve the left side of the body as a rule, it happens that when there is primary left hemianopsia and right-sided anæsthesia, the boy becomes very much confused in speech, and sometimes is paraphasic, the trouble being but transitory. He is sometimes *unable to speak at all*, though *perfectly conscious and in possession of his faculties*. No pupillary disturbance has been noticed at any time. Upon two occasions there was a swelling of gums and tongue, which was not only subjective, but perceived by the mother.

Occasionally he sees prismatic colors and rays before the blindness, but this has been only once or twice. During his early life he had attacks of slight numbness of the hands and feet which were not thought much of, and he had headache as well. He has been a somnambulist.

A second case came under observation a few weeks ago, which in many respects resembles the last.

CASE II. *Hemianopsia; frontal headache; hemianæsthesia; temporary mutism; loss of consciousness.*—Miss J. D——, aged twenty-nine, comes of a neurotic stock; a brother and sister both suffering from incomplete epilepsy, and her mother has had headache and incident hystero-epilepsy. The maternal grandfather was extremely eccentric, and possibly insane, and there is a history of other neurotic disease.

Since her early childhood she has suffered from vertigo and headache, and with the commencement of menstruation she became hysterical. She is at present a healthy-looking woman, somewhat nervous and excitable in manner, but clever, intelligent, and possessing an unusual memory. Her present attacks became quite marked three or four years ago, and during the past eighteen months they have occurred every three or four weeks—without relation to menstruation, and at any time. They are not influenced in any way, except by occupation and excitement, which seem to prevent the frequency of their recurrence.

[1] Untersuchungen über die Lokalisation der Functionen in der Grosshirnrinde des Menschen, p. 63.

[2] New York Medical Journal, June, 1882. Also consult: Phantasieen in einem epileptischen Aufalle, Zeitschrift f. d. Antrop. 1825, iii., i. Hft. 170; Epilepsy with Spectral Illusions, London Lancet, ii., 57, 1850, Rees; Brain, 1880–81, iii., 192–206, Jackson.

She first noticed a unilateral dimness of sight, and afterward a blindness which was sudden and absolute, and she invariably "lost half of the object at which she was looking." Her first attack of this kind was in a railway station, and while looking at the clock, the figures from "XII" to "VI" disappeared. This abolition lasted for a period of ten or fifteen minutes, and shortly after its event she noticed a numbness of the tongue, and pain on the left side. This numbness next appeared in the fingers of the left hand and slowly extended up to the elbow, when it stopped. The right hand next became involved, and after a "furry feeling" of the tips of the thumb and forefinger her hand became "dead and without feeling" as far as the wrist. After continuance of this state for a period which I estimate varied from five to ten or even fifteen minutes, she lost consciousness, and while in this state, made quasi-convulsive movements which were undoubtedly psychical, as she rubbed the hands over each other, and made attempts to remove her rings. She stated that her fingers were swollen, and her sister corroborated this, and an attempt by the latter to remove the patient's rings was attended by considerable difficulty. Two or three minutes after the development of the anæsthesia there is often exquisite pain over the right eye, which augments in severity and extends over the entire head. This lasts sometimes for an hour or so after the attack, and is not relieved by any application.

During the unconsciousness, which is complete, she neither breathes stertorously, bites her tongue, nor shows any epileptic appearance, except it may perhaps be a slight pallor and dilatation of the pupils. It is impossible to arouse her for several minutes. The attacks are often aborted by strong mental effort, or by diffusible stimulants. Upon several occasions she has been suddenly deprived of the power of speech, and could not express herself, but this is exceptional. Such mutism was coincident with the hemiopic stage, and not subsequent to the loss of consciousness.

She has neither menstrual or other disturbance of the pelvic organs. She has slept soundly, and has had dreams nearly every night, but is not a somnambulist. After the attacks she passes large quantities of clear urine. There is no color-blindness.

Physical examination reveals almost nothing except it may perhaps be a suspicious bulging of the left optic disk, and a tortuous and enlarged condition of the veins. The tongue points slightly to the right. There is no erotogenetic sensitiveness.

These two cases present certain symptoms in common which remove them from association with the familiar form of epilepsy; and there is a pathological signification which should lead us to explain their origin by lesions of the occipital convolutions. As I have before said, they cannot be classed with those cases of pronounced and protracted sensory auræ which precede ordinary epilepsy. Gowers found in his large collection of cases that in twenty-six only there was loss of sight preceding the epileptic paroxysm, which was simultaneous in both eyes. In three of this writer's cases the visual aura was preceded by *pain* in the arm upon the same side as that upon which the unilateral visual aura was perceived, and in one case the visual aura was associated with loss of speech. He, however, brings forward no case in which such visual auræ—which, by the by, were of an incomplete, spectral, or other nature—were associated with anæsthesia.

Ross speaks of temporary blindness succeeding attacks, but this is all, and it would seem that when visual loss occurred, either temporary or permanent, with epilepsy, it was commonly a secondary condition.

Ross refers to the temporary hemianopsia which is so familiar to oculists, and details his own case. It appears that he suffered for years from temporary attacks of sudden blindness, accompanied by tension and fulness, lasting for three minutes or more, and always due to excessive use of tobacco.

Many writers have described a temporary and suddenly developed hemianopsia which they explain in various ways, either as the result of toxic or other causes; but no one, so far as I know, has spoken of its association with anæsthesia and the other symptoms presented by the two cases. It is hardly necessary to say that the condition should not be confused with the hysterical hemianæsthesia so admirably pictured by Charcot, and so often seen by neurologists. The unilateral blindness is purely an amblyopia of another character, and is quite frequently connected with achromatopsia and concentric constriction of the visual field.

Todd [1] reported a case, many years ago, of epilepsy in which the patient's attack consisted in a slight headache, insensibility, and anæsthesia of one side of the body, with swelling of the affected arm and affection of speech. There was no impairment of motor power whatever. He had subsequent similar attacks. There are three continental cases which, though not as uniform in their method of expression, are significant in showing how the association of hemianopsia, speech disturbance, and sensory trouble existed in connection with disease of the posterior cortex, which may be briefly referred to in this connection.

Case III. (Traube [2]).—A man, forty years of age, had been an epileptic for seven years and suffered from left hemispasms which subsequently became general. "An aura, consisting of darkness coming gradually over the field of vision from the left side, always preceded the attack. *During the intervals* a left-sided headache and hemianopsia preceded the attack."

A cyst, the size of an apple, was found in the white matter of the right occipital lobe. The cyst, which was filled with serum, was "surrounded by a zone of softening which did not involve either the cortex or wall of the lateral ventricle." No other lesions were found.

Case IV. (Westphal). — "Male, aged forty-two, suffered from left unilateral convulsions without loss of consciousness, and temporary left hemiplegia with loss of sense of pain after such convulsions. During the convulsions patient was aphasic. In June, 1878, left hemianopsia appeared after a convulsion, and continued until his death in April, 1879; during the last few months there was a slight contraction of the left arm.

"The convolutions posterior to the fissure of Rolando on the right side were atrophied and sunken in, and the white matter beneath was softened. The area of softening included the entire white substance of the occipital lobe and of the superior and inferior parietal convolutions. Thalami optici, corpora striata, and internal capsule intact. Microscopic examination showed the optic tracts to be normal." [3]

Case V. (Stenger [4]).—"Male, aged fifty-two, who had been subject to epilepsy for years, had an attack of left unilateral convulsions without loss of consciousness, followed by paresis of the left leg, paralysis of the left arm, and paræsthesiæ in the left hand. The unilateral convulsions recurred daily for thirteen days, when left hemianopsia suddenly developed and a total loss of muscular sense in the left hand occurred. The paresis gradually disappeared, but the hemianopsia persisted till his death, six months after.

"Autopsy showed, besides softening of the first temporal convolution, ventricular distention, extensive softening of the right occipital lobe, and flattening and softening of the right optic thalamus."

Ixner [5] pictorially reproduces cases such as I have described, in which the central lesion was occipital, and confined to the lobus cuneus and lobus quadratus.

In a case reported by Jastrowitz,[6] a tumor in the left occipital lobe involving the præcuneus, resulted in right hemianopsia, and aphasia with inability to read or write.

With this case, however, there was some paralysis of both extremities of the right side and of the facial nerve.

It is unnecessary to further refer to the ample pathological explanation of central hemianopsia. The alternation which took place in my two cases is worthy of further study, and naturally suggests the existence of cortical commissural connection of a delicate kind; and perhaps a lesion involving the optic thalamus.

The recent discoveries of D. J. Hamilton[1] regarding the anatomy of the corpus callosum prove beyond doubt that there are commissural fibres passing from the cells in the occipital cortex, and that this bundle of commissural fibres occupies the *posterior part* of the corpus callosum. It is not difficult to understand how the variation in the unilateral seizure depends upon the enfeebled inhibitory control of one or the other groups of centres.

II.

Attacks of epilepsy with suspension of the function of volitional speech.—The extraordinary character of the inter-paroxysmal state in a patient recently under my observation is one that not only possesses interest because of its medico-legal relations, but on account of an undoubted abolition of the *voluntary* power of speech and the derangement of certain cerebral speech-centres, which have recently been located by Münk in the occipital cortex. In this case the mechanical apparatus of articulate speech and the immediate organs of phonation were in perfect condition, so far as I was able to judge, and the asemasia was temporary.

Case VI.—C. O——, aged twenty-two, is a reporter attached to one of the New York afternoon papers, who received a severe injury of the head when but three years old. He fell from the second story of an unfinished building to the cellar, striking the upper and back part of his head upon a beam. He was rendered unconscious and remained so for a day or more. He recovered from the immediate bad effect, but has suffered from severe general headaches, which recur every week or so, with an increase in the amount of urine excreted. About six months ago he began to have epileptic convulsions of a violent character almost every day, and sometimes more often. These were precipitated by excitement, and he had a great many when worried about his wife at the time of her delivery. Upon one occasion he fell downstairs and injured himself quite severely. The attacks were, as a rule, preceded by an epigastric aura of long duration, and occasionally by a visual aura, and, according to the testimony of his associates, he became strange and queer. When in such a dazed condition he would restlessly wander about his office, and suddenly, without any cry, become convulsed. After the attack he slept soundly. The bromides of sodium and ammonium and digitalis did little or no good, but the bromide of nickel appeared to have some influence. During the past month he has had only two or three attacks, but these have been of a quite irregular character. He told me that there were times when he felt like doing himself an injury, and that he had impulses to kill some one else. His companions said he was irritable, pugnacious, and easily thwarted, and his brother-in-law stated that upon several occasions he had "queer turns," when he would raise his hand to strike some member of the family; that he subsequently knew nothing of his conduct, and when it was detailed to him he appeared greatly astonished.

Mr. O—— came to my office in company with a friend at ten o'clock in the morning of December 27, 1883. He had had one of his attacks at the newspaper office, of rather more severe character than usual, at eight o'clock, with a psychical aura, during the existence of which he was very morose and sullen. Upon recovery he was speechless, though he could communicate by signs. Upon his arrival at my office his manner was composed, and he appeared somewhat dazed. His pupils were dilated, but contracted readily to light. I asked him one or more questions regarding his inability to speak, which he perfectly understood, and when I gave him a pencil and piece of paper, he replied without difficulty in writing. When told to make a great effort to speak he did so, and I thought I detected the words "to-day," but he could not repeat them though he tried and expressed great annoyance. He was unable to utter any sound except a sort of groan, which could not be in any way taken as an element of speech. I examined his larynx, but found nothing which could explain his impaired phonation, and I sent him to Dr. Asch, who found absolutely no abnormal appearances to account for the speech difficulty. The patient could not phonate, and though he made attempts to enunciate the vowel sounds, and the vocal cords were approximated, he made no orderly sound. Dr. Asch found a slight laryngitis of no importance.

The patient went home and remained speechless all day, and was seen by my associate, Dr. G. de Forrest Smith, in the evening. What occurred during and after that gentleman's visit is contained in his notes.

"I was called to see patient about 8.15 P.M. He was lying upon the bed, but had not slept, recognized me and motioned that he could not speak, and I found that he could only say one or two words, and this with the greatest effort, and so all my questions were put so that he could answer them by nodding or shaking his head. He knew that he had had an attack in the morning, that he had seen Dr. Hamilton and Dr. Asch, and recalled various incidents of the day, answering intelligently my questions in regard to them. He indicated by motions that his inability to speak was due to 'a lump in his throat.' When asked if he had any trouble to think of the word he wanted, he shook his head, but shortly afterward hesitated in an answer, and when asked if this was due to his inability to think of the word, said 'yes.' Was asked if he had any loss of power in either side, and he motioned to his right arm and leg, and said that he felt a numbness and prickling on that side. On his grasping my hands with his, the right was perceptibly weaker.

"At one time he seemed confused as to which was his right or left side, and put up both hands, and after looking at first one and then the other in a puzzled manner, at last decided correctly, then smiled apparently at his confusion.

"All this time he had been half lying on the bed. He now intimated that he was tired, put his head down on the pillow and began to belch up wind, and as he appeared about to vomit, I called for a basin; but this was only the beginning of an attack, the muscles of the neck and right side assumed a state of tonic spasm, the extensors predominating so that the head was turned a little to the left and forcibly thrust back into the pillow, and the *right arm* and *leg* were firmly extended. He remained in this position about one minute, then taking two or three full inspirations, put his hand to his throat and *said plainly* 'something had fallen from there.' On being asked 'what,' he replied 'A bone has fallen from my throat.' I told him it was well that the bone had fallen, as now he could speak. 'Why,' said he, 'I have had no difficulty in talking.' On being asked why he had seen Dr. Asch, he said 'Who is Dr. Asch? I never saw any such person.' Further questioning showed that all the occurrences of the day (except those which had taken place immediately before the first attack) were an absolute blank, and he thought it still morning. He asked the time and I told him half-past eight o'clock, in the evening. At this he seemed much surprised and said, 'Why, I went to work this morning, how did I come here?' I then explained to him that he had been ill. After further conversation he said he felt sleepy, and, after resting a few minutes, he arose, put on his slippers, and came out into the room. He walked with difficulty, because of the loss of power in the *right side, which he said felt numb and*

[1] Proceedings of the Royal Society, No. 230, 1884.

sore, as if it had been pounded, also a sensation of pins and needles. After the attack his mind was *perfectly clear, and he could talk as well as ever*, and all that had happened before the attack in the morning he could remember perfectly well; but the interval between the two was a complete blank. His inability to speak seemed due, not to lack of knowledge of what he wanted to say, but rather to want of power to form the words, although there was no paralysis of the vocal muscles. When he did manage to say a word it was invariably the correct one, but it was always done with the greatest effort. The day after the attacks he remained at home; the next day he went to work, but his head felt heavy and confused. Two days after he complained of a 'pressure' on the left side and back part of the head, otherwise he was all right. At this visit he said that after I had left him on the night of the attacks, he intently thought, striving to recall the incidents of the day, and after a time concluded he could remember being at Thirty-third Street, but did not know how he got there. He thought he could recall going to see Dr. Asch, but would not know him if he should see him. I then asked him how questions were answered by him on that day; he answered he did not know, as he 'had not thought of that;' then, after a few moments' reflection, said he must have written the answers. He was then shown some of the answers he had written, which he recognized, and by an effort of memory could recall some of the incidents of writing them. He was still unable to remember anything that occurred after his arrival home previous to the last convulsion."

January 27, 1885. This patient subsequently suffered from several attacks in which the psychical element predominated. His head presented a remarkable deformity, there being a prominence posteriorly which might be compared to a *caput succideum*, only it was entirely osseous. The upper margin was separated from the anterior parts by a deep sulcus.

A case in which a remarkable speech defect was observed is that reported by Dr. Edward B. Gray,[1] of England.

Case VII.—The subject was a little girl aged seven, who in every respect was healthy, well nourished, and an intelligent child. Her skull was firmly ossified, large in proportion to the body *especially in the occipital* half. The parents were alive and healthy. She was one of nine children, two of whom had died, one a little girl of three years, who "had had a very big head," and another a boy, of convulsions, a month after birth. The patient had always been a bright child, and no history of any previous ill-health is known. In the latter part of the year 1859, she had been working very hard in school, desiring to head her class. About Christmas of this year the mother first noticed that she would have a vacant look, would or *could not speak for several seconds*, then would jump and run in a semi-choreic manner, in unusually high spirits. These attacks were so marked as to excite the attention of her playmates. She continued to have these attacks for the next three months (how frequently not mentioned) and then they assumed a graver form. No impairment was noticed in her speech until early in April, after which the fits became more and more frequent, and the speech defect greater. Soon after (April 25th) she entered the hospital, and although by no means a listless child, she was never observed to speak, or laugh, or cry. The organs of speech and facial expression were perfect, the tongue and facial muscles were fully under her control, and in every respect she was well, with the exception of the fits and inability to speak, laugh, or cry.

The fits came on very frequently (almost every hour of the day), without warning, "consisting of lossof consciousness" for about a minute, during which time the head was generally bent gradually forward till the chin touched the sternum, and irregular slight spasms of the muscles of the face and eyes took place. The right hand was generally stretched out in front, the index finger being slightly extended and the other fingers contracted as though she were pointing at some object. The tongue was never bitten. There was rarely any turgescence or lividity of the face. During the fits she used to make feeble guttural sounds, much like the noise of a guinea-pig. There was little intellectual disturbance, and the attacks were quite light.

The child under active treatment recovered entirely and was able to speak, and had during the time she was under observation a temporary disturbance of deglutition.

Dr. Gray, in commenting upon the case, says: "The loss of speech was not due to any want of effort, neither could it be attributed to forgetfulness of the meaning of words, or loss of (mental) faculty of combining them in a sentence. . . . She remembered words well enough, her difficulty was to articulate them. Nor, thirdly, could the loss of speech be ascribed to any paralysis of the muscles of the face or tongue."

Wernicke[1] has investigated the aphasiæ of posterior origin, which undoubtedly include those found which are disconnected with facial or hypoglossal paralysis, and in cases where it was associated with hemianæsthesia without hemiplegia he found a lesion of the posterior part of the posterior third of the internal capsule. He has traced out certain fibres which pass backward "along the outer border of the lenticular nucleus in the external capsule, lying just beneath the upper part of the island of Reil, till they reach the posterior angle of the nucleus, over which they curve and then *enter the posterior third of the internal capsule between the sensory tract from the surface of the body, and the visual tract to the occipital lobe.*" In the cases associated with hemianopsia and anæsthesia, there was undoubtedly some lesion affecting this region, but it is necessary to go a step further to determine its extent in those cases in which mutism is the dominant feature, and in which no visual disturbance of moment existed.

Münk and Krause[2] settled beyond question the existence of certain occipital centres, which *psychically* presided over the muscles of the larynx and others concerned in the movement of the jaws and tongue. Krause conducted a series of experiments upon ten dogs, by extirpation and otherwise, and found that when the mutilation had been made, the dogs lost the power to bark and only uttered a hoarse whine, or the sound such as young puppies usually make. He afterward killed several of the dogs, and found besides the degeneration of the cortical centres he had destroyed, many collapsed and discolored nerve-fibres, especially in the *ganglion mammillare*, through which they passed to go to the larynx.

In these cases, especially the former, the patient's behavior bears out the idea that the mutism simply depended upon the inability to use the various muscles of the larynx in the formation of orderly speech sounds. The tests employed demonstrated beyond doubt that there was no actual paresis, but there undoubtedly existed for a time a complete suspension of function of the cortical laryngeal centres.

(To be continued.)

Benzoate of Ammonia is relied upon by some in enlargements and irritations of the prostate gland, and in hypertrophy of the bladder with alkaline urine. It distinctly renders the urine acid when phosphatic deposits are present. It combines also with the glycocin or sugar of gelatine in the bile, and has some obscure curative relation to some bilious troubles. In jaundice there is a deficiency of glycocin. The dose is fifteen to twenty grains.

THE MOST SENSITIVE AND CREDIBLE TESTS FOR ALBUMIN.

By HENRY B. MILLARD, A.M., M.D.,

NEW YORK.

SINCE my contribution to THE RECORD of May 31, 1884, upon the tests for albumin, I have gone over the ground many times again, both in the way of clinical practice, and in the laboratory, with new experiments.

There is a danger from too many contributions upon this subject, that over-refinement, as it were, the creation of imaginary proteids, etc., in the brain of the practitioner, may perplex in many instances where there is no occasion for doubt. Proper and thoroughly conducted researches, however, should simplify examinations, and diminish instead of creating perplexity.

It should be superfluous to say that the positive determination of the presence or absence of albumin and its approximate quantity is a matter of serious import. But it is not always so regarded. It has not yet been positively shown that the presence of renal albumin is perfectly physiological, that is, that it is ever voided without at least some disturbance of the renal circulation. Its presence without some known cause is to be regarded always with suspicion. Of all the rational and physical phenomena, as microscopic appearances, etc., accompanying renal disorders, the absence or presence of renal albumin and its amount, as shown by frequent and thorough examinations, is one of the most important. But I have known many to assert that to test the urine for albumin by heat and nitric acid are all-sufficient, and that if these do not show it the amount present is unimportant. As will be seen, I give full credit to the value of these tests; my observation, however, is to the effect that even these are, as a rule, used so as not to elicit their best indications: turbidity of urine, dirty test-tubes, and indifferent light, among other things, make them often almost valueless, and in some conditions, without care, they are liable to lead to errors.

I have sometimes been questioned as to the utility or need of reagents that show 1 part of albumin in 200,000 or 300,000 of urine. My reply is, that if it be of sufficient importance to examine the urine at all for albumin, it is extremely desirable to have reagents capable of showing it without error, no matter whether in minute or large quantities, and it is no small recommendation to a test that it will show clearly such a small trace as $\frac{1}{25}$ of a grain in 10,000 grains of urine.

Assuming the most important desiderata in tests for albumin to be: first, *accuracy*, and second, *delicacy*, I will endeavor to show how four, especially, combine these attributes to a considerable or nearly perfect degree, the manner in which I have ascertained their capacities, and the possible sources of error from each.

I have used in my experiments the ordinary dried albumin from blood, used mostly, I believe, in photography, but not chemically pure (artificially prepared and dried egg albumin I have employed to test certain reagents and for comparison), artificial peptones and peptone powders, urine, albuminous and non-albuminous, and lastly, chemically pure serum—albumin made expressly for me by Merck, of Darmstadt, and bearing his seal as chemically pure, a guaranty than which there could be none better. Nevertheless, I have tested this for other protein substances than albumin, but have found none. Of albuminose it certainly contains none. I have also employed solutions of most of the alkaloids in medicinal use, the gum resins, etc.

The reagents which I have found to be of the greatest value are nitric acid, heat, Tanret's test, and my own test of phenic and acetic acid and potash. I will say *in limine* that in testing for albumin, and, especially for minute quantities of it, many precautions are necessary; the test-tubes should be clean and bright, there should be a clear light and some sort of a dark background. When I speak of the possibility of detecting by certain reagents, 1 part of albumin in 300,000, it must not be implied that this can be done without care, and even then its recognition is possible only by very careful observation and some experience.

Nitric acid.—To employ this test, the urine, unless perfectly clear, should be boiled with one-fourth its weight of liquor potassæ and filtered. If minute quantities only of albumin be present, I prefer to put the urine in the test-tube, and let the nitric acid trickle along the side to the bottom.

I have found this test to show 1 part of albumin in 100,000, both in a solution of Merck's albumin in distilled water, and with albuminous urine. It *scarcely* shows it, however, and I think 1 part in 100,000 is the extreme limit. The method of ascertaining the capacities of the tests, I will refer to hereafter.

Sources of errors and objections.—As is known, the urates may show a white zone, which will not, however, be produced if the urine be thoroughly heated by letting the test-tube stand in hot water. It does not precipitate peptones. According to Roberts,[1] it shows mucin, which forms a very light stratum above the albuminous zone; it assumes the form of a distinct haze, quite different from the dense opalescent zone in contact with the nitric acid; on twirling the test-tube the mucin becomes diffused, while the albumin resists a considerable amount of agitation.

Heat.—The urine, if not perfectly clear, should be boiled and filtered as directed above. It should then be rendered slightly acid by the addition of acetic acid, or if not boiled with potash, unless very acid, a drop of acetic acid should be added to three drachms.

I have found it to show 1 part to 100,000 of a solution of Merck's albumen, and about the same in albuminous urine; anything beyond that it did not show. Thus, its sensitiveness appears to be about the same as that of nitric acid. It shows 1 part in 100,000 with rather more distinctness, and more satisfactorily, however.

Objections and sources of error.—The turbidity produced by the phosphates with heat clears up on the addition of a few drops of nitric or acetic acid, but when a scarcely visible cloud from albumin is present, this may be scattered by the addition of a few drops of *any* substance. A most serious objection, however, is that when mucin is present *without albumin*, heat will produce cloudiness. Again, in the urine of cystitis, or where there is much leucorrhœa, even after filtration, acetic acid alone produces a slight cloud, and this is intensified by boiling. Allowance can be made for this when the quantity of mucin is considerable and that of albumen slight by observing the haze produced by nitric acid. According to Roberts the addition of a fourth part of a saturated solution of common salt will prevent the mucin reaction. Nevertheless, I have found the amount of turbidity upon the addition of acetic acid, when there was but a minute quantity of albumen, very troublesome, and sometimes very marked without much cystitis, even after filtering. This circumstance often destroys the value of this test. Roberts also claims to be able to detect 1 part of albumin in 250,000. Careful and repeated experiments have convinced me that it is not so sensitive.

The double iodide of mercury and potassium (Tanret's test), employed by Winckler and others as long ago as 1830 in detecting alkaloids, was first introduced as a test for albumin by Tanret in 1872. Full directions for its proper preparation may be found in my article in THE MEDICAL RECORD of May 31, 1884. It is considered to possess the disadvantage of precipitating not only albumin, but the peptones and all protein bodies; that it precipitates the peptones is certain enough, but these may be distinguished from albumin by disappearing immedi-

[1] Medical Chronicle, October, 1884.

ately upon heating or the addition of alcohol. The resinous compounds disappear by alcohol, and the alkaloids and the urates in excess, that may be precipitated, disappear by heat.

It may produce a reaction with mucin and in purulent urine, even after filtration. The nitric-acid test can be employed to form an idea of the amount of mucin, but, in doubtful cases, the co-operation of the microscope will almost always indicate the causes of disturbance by the reagent.

According to Capitan, this reagent will detect the presence of 0.0035 c.c. in 1,000 grammes, about one-twentieth grain to 16,000 grains, or 1 part to 320,000.

I have found it to show, with Merck's albumen, 1 part in 200,000. Beyond that the reaction was somewhat doubtful. With albuminous urine it showed very easily 1 part in 200,000, and in 300,000 clearly enough, but faintly. So it would appear, as is also the case with the next test I shall mention, either that in the preparation of blood-albumin artificially some of the protein elements may be lost, or that in albuminous urine some protein elements may exist which we know nothing of. Certainly the turbidity produced in the 300,000 parts of urine did not disappear, but was intensified by boiling; nor have I ever found such a reaction with non-albuminous urine, unless in the case of cystitis, etc.

But even if this reagent precipitates all protein bodies, they readily disappear by heat. That these bodies often exist in albuminous urine may be shown in many ways, as, for instance, coagulating the albumin by heat and filtering, when, if peptones be present, they can be shown by various reagents, as Tanret's test and others. I do not wish, however, to dwell more upon this matter of peptones and proteids than is necessary to the elucidation of the action of tests with reference to them. To show, however, that protein bodies may be found where there has not been peptonization, I will instance the following experiment: I boiled in a test-tube a small quantity of Ferre's beef-powder, which I know to be chemically pure and to have undergone no process except drying and powdering. I then filtered it; the filtrate showed no albumin, but gave a precipitate and distinct zone with Tanret's test, picric acid, and my own test of phenic and acetic acid and potash. This disappeared at once by heating. This certainly was neither a peptone nor albumin, but was undoubtedly some protein substance liberated by boiling. How many of these protein substances there are afloat in the blood and urine we cannot conjecture.

My examinations of the artificial peptones, although these may not be exactly similar to those found in the blood and urine, were nevertheless of value, as showing clearly that while certain reagents precipitate albumin and peptones, the peptone precipitate produced by certain ones of these disappear wholly by heat and alcohol, while that produced by others, as picric acid, disappears only in part by heat. I have used many of the solutions of peptone, peptone powders, etc., in the market; none of those that I have used show albumin in the filtrates.

According to Méhu the peptones are not often found in the urine, and there is too great a disposition to refer to them many of the phenomena produced by reagents. In cystitis, blennorrhagia, or severe leucorrhœa, the decomposed epithelia may produce a reaction with Tanret's test without albumin peptones or mucin being present. Due consideration must, therefore, be given to this fact. I often direct women suffering from profuse leucorrhœa to syringe the vagina before urinating.

The phenic-acetic acid and potash test.—This reagent, which has given me great satisfaction, was suggested to me by Méhu's reagent of phenic and acetic acid and alcohol for ascertaining the percentage of albumin. The objection to Méhu's formula is that, while a delicate test for albumin, this disappears upon applying heat, which makes it impossible to distinguish it from the proteids and alkaloids.

My formula is as follows:

℞. Acid. phenic. glacial. (ninety-five per cent.)	ʒ ij.
Acid. acet. puri	ʒ vij.
M. Add liquor potassæ	ʒ ij. ʒ vj.

It is important that glacial, that is, chemically pure, acetic and phenic acid should be used, both for the accuracy of the test and the perfect clearness of the solution. The proportion of liquor potassæ I have indicated is not arbitrary, but has been the result of careful experiment, so that the mixture would be neither too acid nor too alkaline, otherwise, as is well known, a soluble acid or alkali-albumin would be formed. The advantages of this test are, that although it gives a precipitate with strong solutions of quinine and strychnine and the peptones, this disappears readily upon the application of heat and with alcohol; the cloudiness produced by the gum resins and copaiba disappears by alcohol. Though less liable to do so than Tanret's test, it may, like it, produce a very slight reaction in the urine of cystitis, even after filtration. The same means of recognizing the cause of the reaction may be resorted to that are recommended when Tanret's test is used.

Another possible source of error, easy, however, of avoidance, is that an excessively acid urine might form with the acids of the test an acid-albumin, disappearing on the application of heat; or in very alkaline urine an alkali-albumin might be formed; in the first of these cases a little more potash, and in the second a few more drops of acetic acid might be added, when the precipitate would reappear, the cloud, however, produced by protein bodies would not reappear. The necessity of adding either of the above reagents is, however, exceedingly rare. I find that with Merck's albumin this test shows distinctly 1 part in 200,000, and faintly 1 part in 250,000. With albuminous urine it shows 1 part in 300,000, showing, like Tanret's test, a smaller proportion than in Merck's albumin. It produces with 1 part in 150,000, and above that, a light blue tint. Its reaction in 1 part in 300,000 is, however, clearer than by Tanret's test. I need hardly say that when albumin exists in such minute quantities the urine should be clarified, and great precautions should be taken, the urine being allowed to trickle slowly down upon the reagent. In such cases a zone is not formed, but a greenish tinge with Tanret, and a blue with my own test, is produced; with this last, if there be much albumin, a whitish turbidity ensues, or a thick whitish layer.

Method of procedure.—The albuminous urine I employed in the above computations was that of a patient suffering from chronic interstitial nephritis of a mild type; the specific gravity was 1.022, normally acid; there was no cystitis, and it was, except being albuminous, about normal in every way. It contained, by Roberts' method of estimation, one-fifth of one per cent. of albumin, or 1 part in 500.

With this figure to start from, I made dilutions with distilled water of 1 part in 10,000, 100,000, etc. I made a ten per cent. solution of Merck's albumin in distilled water, and the other dilutions from that. In testing for minute quantities, as 1 part to 100,000, and above that, with each of the above tests, I placed side by side with the albuminous solution and urine, distilled water and non-albuminous urine treated the same way for comparison. Even distilled water with nitric acid and my own test will show a faint bluish zone at the point of contact, and it is necessary to be able to recognize the difference.

My experiments with all the substances I have used, and various reagents I have not here referred to, have numbered many thousands. My

Conclusions, as the result of these experiments, are: That nitric acid shows 1 part of albumin in 100,000. Heat shows 1 part in 100,000, but rather more clearly than nitric acid, and in examinations of urine I often find it to show minute quantities of albumin where nitric acid

does not. Tanret's test and my own test will show 1 part in 300,000; the latter test the more clearly; this precipitates fewer of the alkaloids than Tanret's.

Nitric acid and heat show almost exactly the same reaction and percentage with artificial albumin and albuminous urine. Tanret's test and my own show the reaction better in the urine than in the artificial preparation. I think, for practical purposes and ordinary clinical use, we may show with ease, by nitric acid, 1 part in 100,000; heat, 1 part in 100,000; Tanret's test, 1 part in 200,000; the phenic-acetic acid and potash test, 1 part in 200,000; heat showing it more clearly than nitric acid, consequently being more sensitive, and my own test showing it more clearly than Tanret's.

Heat, although somewhat more sensitive than nitric acid, is often quite unreliable from the turbidity produced by it with mucin, and this particularly after acetic acid has been added.

Finally, there are cases in which no single reagent is sufficient, and in which, in order to determine the presence of albumin, the employment of several is indispensable.

TWO UNUSUAL CASES OF APOPLEXY, WITH ANATOMICAL DEMONSTRATIONS.[1]

By GEORGE L. PEABODY, A.M., M.D.,

VISITING PHYSICIAN AND PATHOLOGIST TO THE NEW YORK HOSPITAL.

CASE I.—W. J. F——, aged nineteen years, a native of the United States, unmarried, a collector by occupation, was brought into the New York Hospital by ambulance at 3.30 A.M., December 5, 1884. He was in a condition of coma, and nothing regarding his history could be obtained from him. Later his father came and gave a few facts in his history. The patient had been in perfect health a couple of hours before, and so far as the father knew there was no cause for his present illness. When first seen his pulse was rapid, bounding, and incompressible; his respirations were stertorous; his pupils reacted sluggishly, though they were sensitive to light. He was having general clonic convulsions at short intervals, the convulsive movements being rather more marked upon the right side than upon the left. His reflexes were abolished. On the suspicion of possible poisoning he was given apomorphia hypodermically, which produced an effort at vomiting. His respiration gradually assumed a Cheyne-Stokes character, and his pulse gradually failed till he died at 4.20 A.M., fifty minutes after he came under observation.

The autopsy was made ten hours after death. The body was that of a well-nourished, well-developed man of medium weight. There was very slight œdema of the feet and ankles. The adipose layer was thin, and there was no appearance of external violence.

Head.—The convolutions of the vertex were generally markedly flattened. The vessels of the pia *in the sulci* were congested; on the surface they were anæmic, doubtless from the same internal pressure which produced the flattening. Both lateral ventricles and the third and fourth ventricles were distended by blood, partly coagulated, partly fluid. There was a rent in the floor of the right ventricle, chiefly in the corpus striatum, but also in the thalamus, nearly two centimetres deep, externally to which the brain tissue was hemorrhagic and broken down. On the median surface of the rent the brain tissue was but little changed. A clot of blood, a little longer than a hen's egg, and not quite as thick, lay partly in the rent and partly in the cavity of the ventricle.

The *heart*, which I have the pleasure of showing you this evening, was of normal color and consistency. There was marked hypertrophy of the left ventricle; there was atheroma in both of the coronary arteries near their origin, but not enough to interfere with their lumina. The valves were competent, and there was the usual patch of atheroma in the anterior segment of the mitral valve.

The *aorta* was, as you will see, *very small*. Its diameter at the beginning of the transverse portion of the arch was 1.6 centimetre, and just above the iliac bifurcation it was only one centimetre in diameter.

The *lungs* were congested and œdematous.

The *spleen* was normal.

The *kidneys* presented interesting lesions. The left kidney was, as you will see, very small, measuring only ten centimetres in length. Its capsule was not adherent, its surface was very granular, its cortex was very thin, its markings were indistinct. Both fat and urates were visible to the naked eye in the straight tubes near the papillæ. The microscopic examination revealed very numerous areas in the cortex of completely atrophied kidney tissue, in which vessels and tubes were obliterated, and Malpighian bodies were converted into little balls of dense connective tissue covered by droplets of fat. Fat was also present in the tubes of the pyramids, here and there. The ureter was normal.

The right kidney was abnormally large, as you see, doubtless as the result of a compensatory hypertrophy. It was congested, but careful examination, both by the naked eye and by the microscope, failed to detect any lesion of importance.

The *stomach*, *intestines*, and *liver* were normal.

The *arteries* generally appeared thicker than normal; and microscopic examination of both internal carotids, one common carotid, both renal arteries, also of small arteries in the tissue of the atrophic kidney, all revealed the evidences of the lesion known as endarteritis obliterans in a marked degree. I have placed under the microscope sections of most of these vessels for your inspection, and the condition described will be readily recognized.

In regard to syphilis no history could be obtained. I present the case because of its being somewhat unusual to find these lesions at this age. A careful search failed to detect miliary aneurisms in the cerebral vessels. This does not, of course, preclude the possibility of their existence; but cases enough have occurred in which they have not been found to lead us to believe that the results of Charcot and Bouchard, who found them in eighty-three consecutive cases are, to say the least, unusual. So far as I am aware these results have never been duplicated by other observers.

It is well recognized by pathologists[1] that a normal heart or a normal aorta may rupture under circumstances of unusually high tension. Why not also a normal cerebral vessel? With the increased arterial tension in this case, due to a very general thickening of the arteries, such as has been described, and the hypertrophy of the left ventricle, together with the nephritis and the congenitally small aorta, may not a normal vessel have ruptured and given rise to the hemorrhage? It seems more than likely to me, and it is also in that way that I explain the second case, although there seems to be more likelihood of an aneurismal condition of cerebral vessels in this case than in the one just related.

CASE II.—For the use of this case I am indebted to Dr. W. H. Draper of this city. The patient was a large, unusually well-developed boy, nineteen years of age, of good heredity and habits (except as to a recent overindulgence in cigarette smoking), and was at the time in excellent general health. On the evening of April 5, 1884, after an unusually hearty dinner, in which, however, stimulants had not been partaken of, he ran rapidly a distance of about four hundred feet. Immediately thereafter he complained of an agonizing pain in the head, and an absence of all sensation in his legs, which in a few moments was followed by a convulsion, and this by coma and death. His physician arrived in time to note

[1] Read before the Practitioners' Society on March 6, 1885. (See MEDICAL RECORD, March 28th, p. 360.)

[1] Vide V. Recklinghausen, Handbuch der Allgemeinen Pathologie des Kreislaufs und der Ernährung, p. 824.

the manner of his death, which was distinctly due to a cessation of respiration before the heart ceased to beat.

The autopsy was made sixteen hours after death.

Rigor mortis was well marked, and there was no œdema.

On removing the calvaria the dura mater was observed to be dark in color from the presence of blood beneath it. The convolutions were flattened.

Everywhere between the dura and pia there was a small amount of extravasated blood. This was most abundant about the pons and medulla. In this latter situation there was a large quantity of clotted blood beneath the pia and in its meshes. The vessels at the base were normal, except that both internal carotids appeared thicker than usual and did not collapse as these vessels usually do on being emptied of their blood. There was no appearance of atheroma about them, nor were they at all less translucent than usual. The lateral ventricles were found to contain bloody serum rather more in amount than that of the serum which is usually found in them. The third ventricle was filled by a soft, recent clot, and the fourth ventricle was found completely filled by a similar clot.

The origin of the hemorrhage was found in an extensive laceration of the posterior commissure. On washing away the blood with a very gentle stream of water, this laceration was distinctly visible, and in it were to be seen numerous lacerated vessels, some of them of large size, which had been separated from the surrounding brain-tissue and moved about in the stream of water, being still attached to the brain tissue, each by one extremity, the other being free in the deep laceration.

The iter a tertio ad quartum ventriculum was filled with a coagulum similar in color and consistency to that seen in the third and fourth ventricles.

Microscopic examination of sections of the two internal carotids revealed marked hypertrophy of their muscular coats, the lumen in each being perceptibly narrowed. The other coats were normal. The vessels exposed by the laceration of the posterior commissure were next examined, and upon one of them a distinct varicosity was observed, but no other lesion.

Examination of many vessels from other parts of the brain failed to reveal anything abnormal in them.

The organ of secondary interest was the *heart*. Here there was seen, as is still visible, very slight hypertrophy of the left ventricle, and the endocardium of this ventricle is also seen to be markedly thickened and white. The valves are all competent; but the aortic valve consists of only two semilunar cusps, which are equal in size and evidently congenital. These cusps are both rather thicker than usual, but are smooth, and otherwise healthy in appearance. The coronary arteries are normal, as is also the muscular tissue of the heart.

The *aorta* is much smaller than normal in calibre, as are also the great vessels leading from it. The descending thoracic aorta has an internal circumference of four and a half centimetres. A small patch of atheroma is seen just above the aortic valves. Otherwise its structure appears normal.

Of the other organs the pleuræ, lungs, spleen, kidneys, stomach, and liver were carefully examined and found to be intensely congested, but not to be structurally changed.

In this case, too, the arterial tension was doubtless very high. We have again the congenitally small aorta, the hypertrophied left ventricle, the muscular hypertrophy in the two internal carotids, with the possibility of similar changes elsewhere—all these causes predisposed to a rupture. To them was superadded the increased force and frequency of the heart's action caused by the violent exertion of running after a full meal.

I have the pleasure of showing you the heart and aorta of this case.

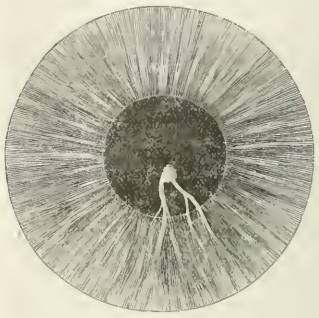
A CASE OF PERSISTENCE OF THE PUPILLARY MEMBRANE WITH ILLUSTRATION.

By F. C. RILEY, M.D.,

LECTURER ON OPHTHALMOLOGY NEW YORK POST GRADUATE SCHOOL; CONSULTING OPHTHALMOLOGIST AND OTOLOGIST NEW YORK INSTITUTION FOR THE INSTRUCTION OF THE DEAF AND DUMB, ETC.

THE persistence of the pupillary membrane with its accompanying phenomena is of interest from the fact of its infrequency. The pupillary membrane is a vesicular structure of embryonic life that covers the pupil during its existence as a series of vascular loops which nearly meet at the point which subsequently becomes the centre of the pupil.

About the seventh fœtal month these vessels begin to be gradually absorbed, and rarely exist after birth. The accompanying cut shows the continued existence of a portion of this membrane, persisting in a male patient who recently consulted me on account of certain painful sensations occurring in his right eye. A cursory examination revealed a small spot, of which he had spoken, on the pupil, which I at first thought to be an opacity of the cornea. Examining by oblique illumination, I could distinctly trace the muscular fibres of the outer iritic circle as they gradually narrowed down to the fineness of a delicate silk thread, running upward from the lower segment of iris, and forming an almost perfect arc as they dipped down into the pupil to unite at a point but slightly below its centre.



Four fibrinous tendrils presented; the two of the left and right side, respectively, uniting before becoming adherent to the lens capsule, but not until after having passed the pupillary border.

The accompanying drawing was made by the patient, with the aid of a concave mirror and condensing lens, and represents most accurately the appearance of the abnormality.

With the ophthalmoscope, with a strong convex glass, the delicate muscular fibre of the iris can be easily traced and its action studied. When the stimulus of light is brought to bear on the eye, the pupil, contracting, shows the adherent fibres lying quiescent in the aqueous humor. As the pupil dilates the outer circle undergoes a contraction, and as these fibres belong to that portion of the iris they contract, and the delicate thread-like processes become somewhat taut, and, doubtless, at times may drag on the anterior capsule of the lens to a slight degree.

The "spot on the pupil" was first discovered some fifteen years since by the patient, while endeavoring to "sight" his rifle. The hole in the sight being but a hair's breadth in diameter, the opacity prevented his obtaining a view of the target through it, and in consequence the left eye was resorted to for such purpose. The test of vision revealed the following: O. D., V.$=\frac{20}{15}$, Jaeger No. 1 at 1 foot; field normal.

He complains of a sense of weakness in the eye at times, especially after long exertion at his professional duties, that of an artist. The contraction of the fan-shaped bundles of muscular fibres that are connected so intimately with the delicate structure of the capsule of the lens doubtless produces an irritation of the ciliary nerve terminals that would account fully for the pain and lachrymation. Neither are, however, very intense, and when they become annoying it is his custom to put over the eye a shade that excludes it from all participation in

the visual act, when a subsidence of the phenomena supervenes.

In connection with the foregoing I may add that a slight conjunctivitis existed which readily yielded to proper treatment.

That the eye is hyperæsthetic to outward irritation there is no doubt, but I am of the opinion it is due entirely to the connection between the iris and lens, there being no refractive error or other lesion to produce it.

ANTIPYRIN IN PNEUMONIA AND OTHER FEBRILE DISEASES.

By LEONARD WEBER, M.D.,

NEW YORK.

Antipyrin was first produced by Dr. Knorr, of Erlangen, and introduced into practice by Dr. Filehne (*Zeitschr. f. klin. Med.*, 1884, vol. vii., No. 6, p. 641). It is an alkaloid derived from chinolin, and, according to its chemical composition, would be "dimethyloxychinicin." A white, crystalline powder, it is freely soluble in cold and warm water, also in alcohol and chloroform, and has a somewhat bitter, but not exactly disagreeable taste. It may be given by the mouth in an aqueous solution with some syrup and a drop of the oil of peppermint, or done up in a wafer; also by the rectum or hypodermically. From one to two or three grammes (fifteen to thirty or forty-five grains) as a single dose has been given to adults, and one-half to one gramme to children. Doses of one or one-half gramme every two or three hours, together four to five grammes *per die*, are generally of good service, and sufficient to keep the temperature at a moderate degree, in typhoid fever, for instance, and may be continued with safety for a length of time.

In order to produce a decided and enduring antipyretic effect with the remedy Dr. Filehne originally advised that six grammes should be given in hourly intervals of two grammes for each dose. That this method is not without danger is shown in a recent report on the use of antipyrin in the Dresden City Hospital, by Dr. Jusinelli (*Deutsche Med. Woch.*, March 5, 1885). After three such doses the temperature fell, in one case of typhoid fever, from 39.6° C. to 35° C., in another from 40° C. to 34 4° C., and in a third from 39.6° C. to 34° C. Dr. Jusinelli did not notice any symptoms of severe collapse in these patients, but reports their condition as by no means comfortable for the time being.

Thus far I have tried antipyrin in about fifteen cases of pneumonia, bronchitis, and scarlet fever, and have either given two or three full doses in hourly intervals, where it was my object to reduce a dangerously high temperature as fast as could be done; or small doses administered once in three hours, in cases in which I desired the temperature not to go above 101°. It will suffice for the purposes of this short communication to recite three out of the whole number of my cases, to show the two different ways in which I have given the remedy, and the results obtained. My first case was that of Clara W——, five and a half years of age, whom I found afflicted with double pneumonia, more extensive on the right than the left side, on December 19, 1884. Temperature in the morning on that day 104.5°, the same in the evening.

December 20th, A.M., temp. 104.5°, slight delirium; 15 grains of antipyrin administered per rectum at 11 A.M. and at 1 P.M. At 5 P.M., temp. 100.5°, sensorium free.

December 21st, A.M., temp., 102.5°; 15 grains of antipyrin by the mouth at 11 A.M. and 1 P.M. At 5 P.M., temp. 100.5.

December 22d, in every respect the same as on the 21st.

December 23d, resolution takes place.

My last case thus far has been that of Mrs. R. N. C——, forty-three years of age, of very spare habit, but nevertheless strong, with a good pulse and decidedly nervous temperament. Within the last ten years she was under my care twice for croupous pneumonia, and made a complete recovery from each attack.

On March 16th, I found her again with pneumonia in posterior portion of right upper lobe, and well-marked but not extensive pleuritis on the right lower side. Temp., 103°; pulse, 106.

The pleuritis was the cause of severe pain, and the latter interfered with the respiration. A blister was applied to the lower right side of the thorax, and Dover's powder and calomel, five grains each, were given.

March 17th.—At noon, temp. 101.5°, pulse 100; pleuritic symptoms better, respiration easier, pain entirely relieved; previous signs of pneumonia more marked, but not extending beyond the lower border of the upper lobe. Patient had slept some during the night, and had two or three loose passages in the morning.

March 18th.—General condition, pulse, and temperature about the same as before. No medicine was given on this nor the preceding day.

March 19th.—At 11 A.M., I found a most alarming change in her condition. Although the pleuritis was better and the pneumonic area had not increased, as far as could be made out, the temperature had risen to 104.5°, the pulse to 110, the respiration to 44 per minute. The patient had become extremely restless, but not delirious; her face was of a dusky hue and wore a very anxious expression; her pulse, though fast, was good and strong; skin dry. Twenty grains of antipyrin were given by the mouth at 2, 3, and 4 P.M. When I saw the patient again at 9 P.M., I found her in a pretty profuse but warm perspiration, which had commenced between four and five o'clock in the afternoon. Temperature had fallen to 100.5°; pulse to 96, soft and somewhat small but regular; respiration, 38. Patient complained somewhat of nausea, but was otherwise comfortable and had no symptoms whatever of collapse.

The perspiration continued more or less all night until the morning of March 20th, and from that day until the 25th, her temperature ranged from 100.5° to 102°; pulse, from 95 to 100; respiration, from 36 to 40. Resolution began March 24th and proceeded gradually, and it was not until March 28th that her temperature and pulse returned to the normal standard.

In a case of scarlatina simplex with high fever in an otherwise healthy girl, seven years old, which I treated in February last, the temperature ran up to 105.5° on the second day after the appearance of the exanthema. From the third to the end of the fifth day I gave the child ten-grain doses of antipyrin every three hours during the day, reducing thereby the temperature to 102°, and keeping it there, without causing any unpleasant constitutional symptoms or influencing the course of the disease in any other way. She had later on a moderate attack of nephritis, but eventually got well.

The literature on the subject of antipyrin is already somewhat extensive, but all observers, I believe, agree, and I with them, that the action of the new antipyretic is prompt and decisive, and almost devoid of the unpleasant and sometimes dangerous symptoms of collapse often seen after full doses of kairin. Beyond a doubt, it has been of signal benefit in the case of Mrs. C——, and it will also be noted, that the temperature in her case did not rise again to an alarming height after the administration of sixty grains of the drug, though its use was not resumed subsequently nor any other febrifuge given to the patient. The remaining twelve cases in which I experimented with antipyrin were not such as to develop abnormally high temperatures, and ten to fifteen grain doses every two or three hours were given with the sole intention to reduce the temperature one or two degrees. The success was in that respect all that I expected. Finally, I believe it to be a good plan to begin in all cases with a relatively small dose, *i.e.*, fifteen to twenty grains for adults, ten grains for children, and wait for an hour or two before giving the second.

25 West Forty-sixth Street, March 28, 1885.

Clinical Department.

TRACHEOCELE, WITH THE HISTORY OF A CASE.

Dr. E. Fletcher Ingalls furnishes us with the report of a typical case of this rare and interesting affection. It was shown at his laryngological clinic at Rush Medical College. The patient was a laboring man, aged fifty-four, who suffered from chronic bronchitis and emphysema. He presented a tumor irregularly hemispherical in shape, about the size of half a hen's egg, and located directly in front of the upper part of the trachea in the position of the isthmus of the thyroid gland. This tumor was firm but elastic to the touch and moved upward and downward with the acts of deglutition, but its movements are much less than those of ordinary bronchocele. Pressure upon it did not materially lessen its size, but when the patient closed his mouth and nose and made a sudden expiratory effort, or when he coughed, the tumor suddenly enlarged to the size of a small orange, and the left side of the neck and supra-clavicular region would bulge out from one-half to three-fourths of an inch. By percussing over these regions and over the tumor, when thus disturbed, decided tympanitic resonance was observed. The larynx was normal and nothing peculiar could be discovered in the limited portion of the trachea which could be seen.

The diagnosis was tracheocele. The disease is a rare one. It occurs oftener in men than women, and in two cases at least it was congenital. The cause cannot always be ascertained, but it is usually some unusual strain on the expiratory muscles. Tracheocele sometimes causes dyspnœa and weakness of voice. In the present case it caused no inconvenience and required no direct treatment.

ANEURISM OF THE POPLITEAL ARTERY.

Dr. W. H. Carroll, of Paterson, reports the following case, occurring in the service of Dr. C. S. Van Riper, at St. Joseph's Hospital, in that city. The patient, a laborer, had noticed, for three months prior to admission to hospital, a swelling on the inner and posterior surface of the thigh, which was quite painful when the limb was flexed. On examination a small oval tumor, about the size of a pigeon's egg, was found lying a little to the inner side of the popliteal space. A distinct heaving impulse was felt on palpation, and on auscultation a bruit was perceptible. Several exostoses were felt on different parts of the limbs. A diagnosis was made of aneurism of one of the recurrent or lateral branches of the popliteal artery. Twelve days after admission the patient, while sitting in a chair, experienced suddenly a severe pain in the tumor, which became greatly enlarged and inflamed. Dr. Van Riper, who saw the case two days later, pronounced it one of rupture of the aneurismal sac and proposed operation. On the following morning, the patient being etherized, an incision six inches in length, was made through the skin and subcutaneous tissue. The muscles being retracted, the sac was exposed, and was found filled with a quantity of dark, clotted blood. This was turned out and the sac was thoroughly washed with a two and a half per cent. solution of carbolic acid. It was found that the rupture had been caused by the pressure of an exostosis situated near the inner bifurcation of the linea aspera. This was removed by the bone-forceps, and the femoral artery was then ligated at the lower end of the Hunterian canal and at the lower boundary of the popliteal space. The Esmarch bandage being then removed, it was found that a small opening existed in the popliteal vein. An attempt was made to ligate the vessel, but its coats were so soft that the ligatures would not hold. The vein, and as much as possible of the surrounding tissues, were then seized by the clamp-forceps and the latter were left *in situ*. The edges of the wound were then approximated by silk sutures, and dressed with iodoform and absorbent cotton. The patient was somewhat exhausted, but rallied under the influence of stimulants. On the sixth day the clamp was removed. The wound healed kindly, and the patient made a good recovery.

SYMMETRICAL DRY GANGRENE (SYPHILITIC ?).

Dr. Judson C. Brown, of Syracuse, N. Y., reports the following history, suggested by Dr. S. C. Clayton's case, of which an account was published recently in The Record: H. E——, widower, aged about sixty-three, occupation bartender. His health had always been good until a year ago, when his hands began to swell and became very painful. This condition having existed about three or four weeks, the last phalanges of his left hand began to sphacelate together, with three or four of those of his right hand. In looking about for a cause none could be found except syphilis, which he had contracted during the war, and of which he supposed himself completely cured. His treatment consisted of mercury and iodide of potassium, put together with local palliative measures. Gradually the line of demarcation formed. Amputation was advised by some of the physicians who saw him, but the patient refused to allow it. He came under my professional care about July 1, 1884. His treatment during last summer was mostly sustaining without specific medication, with an occasional shaving off of the dry and blackened tips of his fingers with a scalpel. This condition continued until, financially exhausted, he entered the St. Joseph Hospital, of this city, where he is to-day patiently waiting for nature to amputate his fingers, which she is certain to accomplish in time. Dr. Brown suggests that an early amputation would have been the wisest course in the case.

COCAINE.

We present below some additional reports concerning the use of cocaine in the production of local anæsthesia.

Dr. M. E. Alderson, of Russellville, Ky., writes that he applied a four per cent. solution to several ulcers of the rectum, and in fifteen minutes was able to cauterize them without exciting any spasm, and with the production of scarcely any pain, although some months before the same application had caused severe pain and spasm of the sphincter. By means of the same anæsthetic, he was able to inject some hemorrhoidal tumors without the production of any sensation to the patient.

Dr. A. E. Loewenthal, of Hoboken, N. J., was called upon to remove a cancerous tumor of the vagina, and, as the patient was exhausted by hemorrhage, he decided to employ local anæsthesia by cocaine rather than to use ether. The tumor was painted with a five per cent. solution for a period of about fifteen minutes, and was then excised with the Pacquelin knife. Cocaine was then applied anew, and the surface of the wound was thoroughly scraped, and finally the actual cautery was used to arrest the rather copious hemorrhage. The patient experienced no pain at all until the hot iron was used, and then complained but slightly.

Dr. Charles N. Dixon Jones, of Brooklyn, sends reports of a number of cases in which cocaine was used with the usual satisfactory results. The first was one of very sensitive urethra in a man, sixty years of age, suffering from stricture. Five minutes after the injection of fifteen minims of a four per cent. solution a sound was introduced and the stricture dilated without pain. The writer now uses an iodoform ointment, to which is added a small percentage of cocaine, to anoint his urethral instruments, with the result, he thinks, of greatly lessening the pain attending their passage. On another occasion he incised

the meatus without pain, and with the loss of but two or three drops of blood, after a previous application of a four per cent. solution on absorbent cotton. The third case was of excision of the tonsil. The fauces, tonsil, and wall of the pharynx were painted with the same solution, and the gland was removed without pain, although the patient could feel the knife dividing the tissues. Finally, a case of acute coryza and conjunctivitis was almost immediately relieved by a local application of the drug.

Dr. Frank C. Larimore, of Mount Vernon, O., relates a case of pulmonary and laryngeal phthisis, in which the suffering from dysphagia was extreme. By means of cocaine, applied three times a day to the ulcers on the epiglottis, vocal cords, and aryteno-epiglottidean folds, such relief was obtained that the patient could eat heartily and without the slightest pain. The applications were made regularly for three weeks, when death occurred from the pulmonary trouble.

A CASE OF TRICHINOSIS.

Dr. C. F. Damall, of Walnut, Iowa, writes that he was called to see a German woman, supposed to be suffering from chronic rheumatism. She was in a typhoid condition—morning temperature, 102.5°, evening, 105°; pulse 140; respiration, 36 to 40. There was puffiness of the face, dysphagia, dyspnœa, hoarseness, flabbiness of the muscles, pain on voluntary motion, and excessive and constant perspiration. The tongue looked like a piece of raw beef; the spleen was enlarged and painful; there was obstinate constipation, some tympanites, but no other signs of gastro-enteric irritation. The patient suffered from constant thirst, there was no appetite, and scarcely any sleep could be obtained. A diagnosis of trichinosis was made, and was confirmed after the patient's death, which occurred four days later. The woman had eaten no raw pork since coming to this country, in November, but had done so before leaving Schleswig-Holstein, in October. Immediately after eating the pork at this time she was taken with vomiting and diarrhœa, and was sick for about a week. After that pains were felt in the flexor muscles, and in the back and neck, but only when attempts at voluntary movements of the limbs were made.

A REMARKABLE CASE OF HYSTERIA.

Dr. T. B. Camden, of Parkersburg, W. Va., sends an amusing report of his investigation into the wonderful case related by Dr. J. P. Shafer in The Medical Record of November 22, 1884. He accompanied the doctor, by invitation, on three different occasions in May last, to the patient's house, and witnessed the alleged transit of the calculi from the kidney to the chamber vessel. The incidents of the first visit he describes as follows: "The doctor, after a bedside lecture on his mode of passing the calculi from the ureter and kidney, asked the patient if she felt any gravel. She located those along the course of the ureter. The doctor placed two fingers over the parts, proceeded to pull and push, stopping at times to have her locate the gravel, and keeping up the manipulation, and gradually bringing them along the supposed course of the ureter until he got *an inch above the pubes*, when he made steady pressure, remarking that the lady could tell when they slipped into the bladder by loss of pain. She said: 'There, it is in.' Another and a third were landed the same way, and all found the *new* entrance of the duct into the bladder just an *inch above the pubes*. The doctor remarked that at a certain point in the journey they caused the patient to 'jerk'—and she 'jerked.' The doctor would have me try my skill at the new feat, but, from lack of faith or awkwardness, I failed. The operation was not very painful. I have seen patients suffer agony in passing a renal calculus, so that opiates and chloroform had to be resorted to; but three were passed in this case in a few moments, and we all seemed to enjoy it. 'Now,' said the doctor, 'I have them in the bladder, I will introduce this catheter.' (It was a large female gum catheter, with a large eye.) 'She will then get up over the chamber, and pass the calculi through it into the vessel. If any are too large to pass through the catheter she will catch them *in the eye* of the instrument and pull them out.' I was struck with the skill necessary to scoop one into the eye. She got out of bed and over the vessel and soon we heard something drop, drop into it. 'There they come!' said the doctor. She soon produced the catheter from under her clothes and, sure enough, a big, rough, irregular stone peered from the opening. It almost smiled at me. Both doctor and patient appeared well pleased. I was presented with the find, 'which they both regretted was not larger.'"

Dr. Camden remarked that some of the stones were rather large to have passed through the catheter, and was answered by Dr. Shaffer that he also had observed the same fact, but presumed that it was due to the "peculiar expansive power of the urine over the gum." Among the stones taken from the chamber after the operation was a coal cinder. This was shown to the medical attendant, who ventured the suggestion that its presence might have been accidental. Upon being invited a second time to be present at the *séance*, the writer prepared a cork to fit the catheter and drilled in it a small hole of just sufficient size to allow a stream of water to pass. This he managed to insert into the catheter unobserved. The previous operation was repeated in all its details, and the stones rattled into the vessel with just as much ease as if the catheter had not been plugged. Still a third time the invitation to witness the manipulation was extended and accepted, and again the cork was slyly introduced into the catheter. But the stones laughed at all obstacles and dived into the water as before. Each time also one large fellow was deftly captured in the eye of the instrument. An attempt was made to pass some of the pieces of stone through the catheter, but they were far too large. The stones were all, the cinder of coal excepted, of the same general appearance. They were almost flat, comparatively smooth on one surface, and somewhat nodulated on the other, while the sides were very rough and showed unmistakable evidences of fracture. They were on an average five-eighths inch long by three-eighths inch wide, some being larger and some smaller. Some of them were examined by Curtis C. Howard, an analytical chemist of Columbus, O., who reported that they resembled ordinary limestone in composition, and "could not have been formed in the human body." The little ruse with the cork was explained to the attending physician, but "he insisted that the stones must have come from some place, and he was sure he could not have been deceived."

[In publishing Dr. Shafer's letter we added the comment that it appeared to be one of hysterical simulation. The reading of Dr. Camden's letter, and an examination of the specimens forwarded, leave no doubt that he has correctly interpreted the case. Dr. Shafer has also sent us on several specimens, and reasserts his original view that the case is a genuine one. In charity we must believe that he is imposed upon, as his specimens look like anything but renal calculi.—Ed.]

The Supply of Medical Men in Prussia.—During the official year 1883–84, 460 doctors of medicine and students presented themselves for the State's examination in the Kingdom of Prussia, against 404 in the previous year. Of the nine centres for examination, that of Berlin gave the worst results. Here 184 presented themselves, and 62 failed or withdrew. Königsberg was not much better; 36 presented themselves, and 15 failed. At Halle 42 were examined, and only 3 failed; while at Bonn 33 were examined, all of whom passed. Of the total number presenting, 125 failed, or twenty-seven per cent.

Progress of Medical Science.

Muscle-Grafting and the Regeneration of Muscular Fibres.—Dr. Eduardo Salvia has recently published at Naples a memoir embodying experimental researches on muscle-grafting (London *Lancet*, January 31, 1885). He recalls that Gluck was the first to prove, experimentally, that muscular tissue detached from a living animal has the power, when introduced into the tissues of another animal, of contracting organic adhesions and continuing to live. He observed that by adopting certain precautions, chiefly of antisepsis, pieces of muscle, without tendon, might be transplanted in rabbits and hares, and remain in the part grafted as true muscular tissue. If, however, the graft excited inflammatory reaction of some intensity, the histological characters of the engrafted tissue underwent fibrous metamorphosis. In 1882 Dr. Helferich, director of the surgical clinic in the University of Munich, sought to put to practical use the knowledge so far acquired by experiments in muscle-grafting. His clinical note, published in the *Archiv für Klinische Chirurgie*, embodies notes of a case worthy of reproduction. In removing a sarcoma from the front of the right arm of a lady, aged thirty-eight, Dr. Helferich had been compelled to excise a considerable part of the biceps, which had become infiltrated with the pathological product. Nearly the whole of the upper half of the biceps was removed; only a small bundle of muscular fibres as thick as a slate-pencil being left, on the outer side, continuous with the tendon. The resulting space was exactly filled with a piece of muscle, weighing three ounces and two drachms, detached from the thigh of a healthy dog just at the moment of grafting. Care was taken to insure accurate adaptation of the muscular surfaces, without bagging; and the grafted muscle was secured to the remaining portion of the biceps with thirty points of catgut suture. Some counter-openings were made in the skin for drainage, the external wound sutured, and a Listerian dressing applied. The arm, bent at an acute angle, was fixed to the thorax. The operation was performed with strict regard to antiseptic rules, but without spray. The process of recovery was uneventful. The first dressing was only on the ninth day. In consequence of detachment of some of the sutures, the lower angle of the wound gaped somewhat; and through it issued a necrotized fasciculus of the engrafted muscle, when a carbolized solution was injected through the drainage-tube. The piece of separated muscle was as long as the canine portion inserted, and about one-eighth its depth. On the eighteenth day a piece of skin as large as a shilling sloughed at the point of issue of the mortified muscular fasciculus. A month later the patient had completely recovered; but the limb was somewhat œdematous. After employing for two months constant and induced currents of electricity, the right biceps muscle regained its normal electro-motor power, alike on the right side, where a part of the original muscle remained, and on the inner side, corresponding to the engrafted muscle. The patient could move the forearm with power, and without the slightest pain, alike in pronation and supination. Dr. Salvia's experimental researches were instituted with a view to ascertain if it be possible to transplant muscles between animals differing in species, food, and habits. After a number of failures he succeeded, under strict antiseptic precautions, in engrafting into the thigh of a dog a portion of the rectus femoris of a rabbit. So perfectly did the transplantation succeed, that no trace of it could be discovered by the naked eye or the microscope when the dog's thigh was dissected three months later. Reviewing all the steps of his research, Dr. Salvia has felt justified in formulating the following propositions: First, it is possible to transplant a piece of the muscular tissue of an animal among the cut muscular fibres of another animal, although the two may be of different species. Secondly, the piece of transplanted muscle may become thoroughly united with the muscle into which it is grafted, without exciting suppurative or specific inflammation. For the attainment of this result it is necessary that the piece of transplanted muscle should completely fill the space resulting from the retraction of the ends in the excised muscle. It is equally necessary that the operation be carried out with the strictest antiseptic precautions. Thirdly, the union between the fibres of the transplanted muscle and those of the animal grafted takes place by new formation of young muscular fibres; these become immediately continuous with the fibres of the animal and of the graft, without leaving any trace of the primary point of separation. Fourthly, the grafted muscular fibres gradually lose their distinctive anatomical characters, acquiring those of the animal's fibres in which they live; no difference between them can, after a certain time, be detected by the most careful microscopical examination. Fifthly, the function of the muscle after the graft is perfectly restored, and that comparatively quickly, without the slightest indication of weakness or torpor.

The Treatment of Foul Wounds by Hot Air.—A correspondent of the *Lancet* writes concerning the above as follows: "The perusal of Mr. Kesteven's interesting paper on antiseptic steam irrigation of foul wounds induces me to offer you a description of a method of treatment by hot air that for some years I have used with marked success in cases of chronic, indolent, and varicose ulcers, syphilitic or otherwise, which are known to every practitioner, and are a source of annoyance to the patient and his friends from their offensive discharge. I employed a village carpenter to make the box I used. It is constructed of well-seasoned wood, the bottom, or floor, consisting of three layers about an inch apart from one another, the outer one, of stout sheet zinc or tin plate, is that against which the flames of the spirit-lamps impinge; the middle is of perforated zinc, and above that a wooden floor, also perforated by numerous holes. The apparatus is placed on the bed, and the limb put in it by lifting the two lids which are perforated by holes for the escape of hot air and vapor; the spirit-lamps, two or three in number, are lighted, and the temperature is quickly raised within the box to as great a height as can comfortably be borne by the patient, and maintained for two hours, the process being repeated morning and evening. Sprinkling the inside of the box with an ounce or so of terebene is of value in neutralizing the offensive smell from a large ulcer, and also probably contributes to the stimulative effect of the hot air. In syphilitic cases calomel may be vaporized by sprinkling on the zinc floor above the lamps. Before placing the limb in the box I well wash off as much purulent matter as possible with a syringe and a solution of boracic acid. After removal from the box I apply a piece of lint cut to the shape of the wound, but a quarter of an inch smaller, and soaked in a saturated solution of boracic acid, and either no bandage or just enough to keep the lint in place. I need hardly add that the rapidity of healing will be greatly accelerated if the patient will maintain the horizontal position entirely during the treatment; in other words, keep his bed or sofa. I have found large chronic ulcers of many years' standing heal rapidly under this process, and the limb remain sound and useful for years with the help of an elastic stocking or bandage. I think both Mr. Kesteven's experience and my own go to prove that in heat we have a manageable as well as powerful stimulant which is undeservedly neglected in treating the class of cases referred to."

Vomiting of Pregnancy.—Dr. Galceran reports a case of very severe vomiting of pregnancy which had resisted every effort to control it, but which was arrested at once by the application of ether to the epigastrium. The vomiting began again at two different times, but was controlled immediately by a fresh application of ether.—*Rivista Clinica*, February, 1885.

Tracheotomy in a Child Two Months Old.—Dr. J. Hassing, of Copenhagen, relates in the *Hospitals-Tidende* of January 14, 1885, the case of an infant two months old, suffering from congenital syphilis, who was suddenly seized one morning with intense dyspnœa, and was brought to the hospital in a cyanotic condition. An attempt to induce emesis having proved unsuccessful, and the dyspnœa increasing, tracheotomy was decided upon. The operation was performed at once and the edges of the wound were retracted by silk sutures, no canula sufficiently small being at hand. The urgent symptoms were immediately relieved, and the patient made a good recovery. There was evidently stenosis of the upper part of the respiratory tract, but the exact seat of the obstruction was not definitely ascertained. It was thought, however, to be due to œdema of the glottis from catarrhal laryngitis.

Helenine.—This is a new antiseptic which has been brought forward within the past few months. It is a concrete volatile oil, crystallizing in quadrilateral prisms, and derived from *inula helenium* or elecampane. It was discovered as long ago as 1660 by Lefebre, pharmaceutist to the king of France, but its medicinal properties were described only recently by Korab. It diminishes all the secretions, especially of the trachea and larynx, and will in small quantity prevent the sialogogue and diuretic action of jaborandi. It is a powerful antiseptic, one centigram (about $\frac{1}{7}$ grain) being sufficient to prevent putrefaction in a litre ($1\frac{3}{4}$ pint) of urine. On account of its antiseptic properties and of its affinity for the respiratory mucous membrane, it has been proposed as a remedy for pulmonary tuberculosis. Dr. Baeza has been studying this drug (*La Crónica Médica*, February 5, 1885) and has found its claim as an antiseptic to be well founded. We hope to be able to refer again to these experiments, which are not as yet concluded.

Electro-puncture in the Treatment of Lead Palsy.—Dr. Lopez Alonso relates the case of a man thirty-six years of age, a printer, who suffered from severe lead-poisoning. The hands and fingers were flexed and the electrical contractility in the extensor muscles was abolished. Not being able to produce contractions with the strongest currents when the electrodes were placed on the skin, the writer bethought himself of electro-puncture, which he had already employed in the preliminary examination. By this means the muscular contractility was revived, and after a few days reactions could be obtained with electrodes placed on the integument. In about a month the wrist-drop was cured and the patient was able to resume his occupation of type-setting.—*Revista de Medicina y Cirugia Prácticas*, February 7, 1885.

Prolonged Baths.—Dr. Danchez relates a case of gastric hysteria, with intractable vomiting, of two months' duration, in which a cure was obtained in a short time by means of tepid baths continued for from four to eight hours and repeated once a day. This mode of treatment has also been used with advantage in acute mania and in other nervous affections, in psoriasis and prurigo, and in surgical injuries. The baths should last from three to eight hours, and the temperature of the water should be maintained at a uniform height throughout. The water should not be too hot, but may range from 68° to 82° F., provided the temperature decided upon be kept invariable.—*Rivista Clinica*, February, 1885.

A Symptom of Meningitis.—From the study of a considerable number of cases of meningitis, Dr. Kering has convinced himself of the presence of a symptom which hitherto has attracted but little attention. In the majority of cases the classical symptom of rigidity of the neck and back is present, and in a few there are also contractions of the extremities. But in many cases, the author says in most, while there is rigidity of the neck and back, there is not any of the extremities as long as the patient lies in bed. If the legs or arms become flexed they can readily be straightened again. But if the patient be raised and placed, for example, sitting on the edge of the bed so that the legs hang over, the limbs become markedly rigid, and there is even a contracture of the knees and sometimes of the elbows in the flexed position. If now the patient be placed in the erect posture, the contractures disappear, and return again when the former sitting position is resumed.—*Raccoglitore Medico*, February 28, 1885.

Subcutaneous Urethrotomy.—In a letter of Dr. Eugenio Casati, from Vienna, to the *Raccoglitore Medico* of February 28, 1885, is described Dittel's method of performing urethrotomy. It may be called subcutaneous external urethrotomy. A large grooved sound is first introduced and passed down to the seat of the stricture, the groove looking toward the posterior part of the urethra. Then a rather slender tenotome is introduced beneath the skin and passed down until the point engages in the groove of the sound when it is driven forward, cutting the stricture from within outward. The writer states that the operation has given excellent results in Dittel's hands, but it is one that requires some skill, since it is performed as it were in the dark, and the operator can be guided by the sense of touch alone.

Treatment of Sprains.—According to M. Marc Sée there are two indications in the treatment of sprains: 1, To provoke rapid absorption of the fluid effused around and within the joint; and 2, to favor cicatrization of the torn parts by immobilizing the articulation. Now, the modes of treatment hitherto in vogue do not fulfil these two indications. Massage would seem to present some real advantages, but it can be of little service in the case of severe sprains, and mild injuries would probably do as well under rest alone. M. Sée advises an elastic bandage, the depressed parts being covered with a layer of cotton so as to prevent too great pressure over the prominence, and thereby causing sloughs. This bandage acts like massage in promoting absorption and also secures immobility of the joint. It is of equal service in sprains complicated with rupture of points of insertion, whereas massage would be productive of harm in cases in which splinters of bone were torn away.—*Revue Médicale*, January 31, 1885.

The Injection of Hot or Cold Water in Uterine Hemorrhage.—Dr. Schwarz relates a case of post-partum hemorrhage which was controlled temporarily by an injection of water at a temperature of 120° F., containing two and a half per cent. of carbolic acid. The bleeding began again, however, and could not be arrested by further hot-water injections. A trial was then made of ice-water with perfect success. In other puerperal and non-puerperal cases, after failure with hot water the author obtained most satisfactory results with cold injections. Dr. Graefe has also had several cases in which he found cold irrigations to answer the purpose after hot water had failed. He regards the styptic action of hot water as due not only to the swelling of the tissues which it causes, but also to a certain degree of muscular contraction in the uterine walls. The former is not sufficient in itself to arrest the hemorrhage unless aided by muscular contraction. When cold water irrigations follow those previously made with hot water strong contractions of the uterine muscle are excited, but the œdematous swelling caused by the hot water cannot be so rapidly overcome, and hence the two conditions most favorable for arresting the hemorrhage are present. In the same way, when hot injections follow cold ones the irritation to the muscular tissue remains and to it is added the swelling of the tissues above mentioned. If only one be used Schwarz prefers the cold water, as having the advantage of absolute safety. Hot water, if too hot, may cause a paralysis of the uterine muscular tissue, and if not hot enough will only increase the hemorrhage. If a trial with one temperature be unsuccessful, the use of the opposite will almost certainly control the bleeding.—*Schmidt's Jahrbücher*, No. 7, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 4, 1885.

ORGANIZATION OF THE INTERNATIONAL MEDICAL CONGRESS.

WE have received a copy of the Rules and Preliminary Organization of the Ninth International Congress, to be held in Washington, D. C., in 1887.

The regulations as to membership of the proposed Congress are as follows: As regards foreign members, it is only required that the person be a regular physician, that he shall inscribe his name on the Register, and take out tickets of admission.

The American members of the Congress must be appointed by the American Medical Association, by regularly organized State and local medical societies, and also by such general organizations relating to special departments and purposes, as the American Academy of Medicine, the American Surgical Association, the American Gynecological, Ophthalmological, Otological, Laryngological, Neurological, and Dermatological Societies, and the American Public Health Association; "each of the foregoing Societies being entitled to appoint one delegate for every ten of their members."

It is requested that all societies entitled to delegates elect them at the last regular meeting preceding the meeting of the Congress.

The work of the Congress is to be divided into nineteen sections, as follows: 1, Medical Education, Legislation, etc.; 2, Anatomy; 3, Physiology; 4, Pathology; 5, Medicine; 6, Surgery; 7, Obstetrics; 8, Gynecology; 9, Ophthalmology; 10, Otology; 11, Dermatology and Syphilis; 12, Nervous Diseases and Psychiatry; 13, Laryngology; 14, Hygiene; 15, Collective Investigation, Nomenclature, and Vital Statistics; 16, Military and Naval Surgery and Medicine; 17, Practical and Experimental Therapeutics; 18, Diseases of Children; 19, Dental and Oral Surgery.

These sections are organized with a President, one to seven Vice-Presidents, a Secretary, and a Council of from four to fifteen members. In the selection of various officers, the Committee has, on the whole, displayed excellent judgment, and neither sectional nor ethical prejudices have been allowed to appear. Possibly it may be claimed that the East has more than its share. Among the nineteen presidents, five are from New York, four from Philadelphia, two from Boston, Cincinnati, and Chicago, respectively, one each from Rome, Ga., St. Louis, and Louisville. The largest section is that of Surgery, of which Dr. David W. Yandell is President; Dr. J. M. Da Costa is President of the Section on Medicine; Dr. Reamy, of Cincinnati, President of the Section on Obstetrics.

The policy of dividing the work of the Congress into nineteen sections is open to much criticism, and is the result, we fear, more of personal than of scientific considerations. The consequence must inevitably be that the individual members can hope to hear and see but very little of the Congress outside two or three sections. The subdivisions, for example, of such subjects as Hygiene, Vital Statistics, and Medical Legislation, seems hardly called for. It is ungracious, however, to criticise the work of the Executive Committee at this stage, when it has coped so successfully, in most respects, with the difficult task of preliminary organization.

We would, in conclusion, suggest that the Executive Committee cause to be corrected a very manifest grammatical blunder in the first Rule of Organization, quoted by us above. It is unfortunate that a document which is to have an international circulation should start off with a solecism.

THE CHILDLESSNESS OF LITERARY WOMEN.

THE recent publication, by Mr. Cross, of the Life of George Eliot, has called special attention to the subject of distinguished literary women. Literary women are a product of the last hundred years. Before that time famous women were made so by the accidents of history, or because their genius or character led them into political, religious, or social prominence.

A survey of the lives of later and literary women shows us two things: first, that most of them were either single, or if married were childless; and second, that they have been generally long-lived. The list of literary spinsters includes Fredrika Bremer, Emily Brontë, Hannah More, Harriet Martineau, Eliza Cook, Miss Sedgwick, Gail Hamilton, the Carys, Miss Dickinson, Maria Edgeworth, Miss Mitford, Augusta Evans, Jane Austen, while that of childless women includes Mrs. Nichols (Charlotte Brontë), Mrs. Somerville, George Sand (?), Mrs. Cross (George Eliot), Mrs. McLean (Letitia E. Landon). Several have had one or two children only; for example, Mrs. Barrett Browning had one son, and Madame Darblay one son, Madame De Sevigné two children, Madame De Staël also had children.

It is no doubt true that both men and women of distinguished intellectual talents, and who are active brain-workers, are liable to be childless, or to have but few children. The world would soon be depopulated if it were filled with persons of great intellectual stature. Physiologists assert that the diversion of force brainward leaves an insufficient amount for the needs of propagation.

The longevity of female brain-workers is simply in accordance with the established fact of the longevity of masculine brain-workers. Thus, Hannah More died at the age of eighty-eight; Mrs. Somerville, at the age of ninety two; Miss Mitford, at the age of sixty-nine. At the time of her death Madame De Sevigné was seventy, Miss Bremer sixty-four, Miss Edgeworth eighty-two, Madame Darblay eighty-eight.

OVER-PRESSURE IN AMERICAN PUBLIC SCHOOLS.

One might expect that in America, if anywhere, the results of over-pressure in the education of children would be felt. The children here are generally ambitious to get ahead, if not to study, and parents are often more anxious to get their children settled in the world and at work earning money, than to see them carefully educated. Some years ago the late Dr. Clark, of Boston, woke up our educators with some striking facts regarding the evils of over-pressure in the education of girls. Since that time a knowledge of these evils has been kept well before the public, and, indeed, so much so, that for a time a kind of educational panphobia prevailed. A fear lest the child should have its health injured by over-study prevailed decidedly over the desire for a sound mental training.

This feeling, undoubtedly, did much good in awakening an interest in physical culture, but it was, in many cases, carried too far. Just now an agitation has been started in England regarding over-pressure in the London public schools. This agitation has started, or been coincident with, an investigation of the public schools in this city.

It has been stated that there is over-pressure and "cramming" in the last two grades of the grammar schools, in order to enable the pupils to pass the examinations for the college. A committee of the Board of Education has been appointed for the purpose of considering the matter, and, if deemed needed, of rearranging and lengthening the courses. From the evidence furnished by commissioners and teachers, there seems no doubt that some change is needed.

So far as actual physical and mental injury, caused simply by over-pressure in schools, is concerned, medical men see little of it, and it exists mainly in the imagination of the anxious and the sentimental. School-children in cities become ill mainly because they live badly at home, and because the school houses are overcrowded and ill-ventilated. Evils result also from the hard-and-fast methods of grading, but the number of pupils made ill by excessive mental work is very small.

DISSOCIATION OF THE AURICULAR AND VENTRICULAR MOVEMENTS OF THE HEART.

Professor A. Chauveau reports in the *Revue de Médecine* a case so unique and striking, that we at once present a brief account of it to our readers. It was that o a man, a patient in the service of Professor Boudet, who had a radial pulse of only twenty-one to twenty-four beats per minute. Upon auscultation, and by means of sphygmographic tracings, it was found that, while the ventricles beat only twenty-one to twenty-four times per minute, the auricles pulsated sixty-six times. These auricular pulsations were tolerably regular, but were perfectly independent of the ventricular rhythm, being sometimes presystolic, sometimes post-systolic.

Professor Chauveau adds the results of his investigations as to the pathogeny of this condition. By cutting one of the pneumogastric nerves in a horse, he obtained some dissociation in auricular and ventricular movements. But by slightly stimulating by a galvanic current the left vagus, he obtained a sphygmographic tracing of dissociated rhythm which almost completely resembled that obtained from his patient. The inference is that a slight irritation of the vagus is a cause of the dissociated movements. The case throws light, therefore, upon the pathology of dissociated rhythm of other types than the unique one here described.

THE DRUG TRADE.

The sale and use of drugs, excluding those employed in the manufacture of patent medicines, is, in a certain measure, an index of the professional activity of medical men. Judged by this, the year 1884 just passed was not an especially unfavorable one, but the contrary. In his "Annual Review of the Drug Trade of New York" for 1884, Mr. D. C. Robbins says that the statistics of the imports of goods into this country show an exceptional gain in the total sum of imports in the drug trade, and that as compared with other business this trade has suffered less.

The total import of dutiable and free drugs and chemicals in 1884 was valued at $52,063,910, as against $50,867,165 in 1883. This gain was entirely in the free list, while there was an absolute falling-off in dutiable articles.

With regard to quinine, it appears that we are every year importing more, and are manufacturing less, since we import less cinchona bark. In 1884 we imported 1,263,732 ounces of quinine salts, and 2,588,307 pounds of cinchona bark, as against 794,495 ounces of quinine and 5,010,547 pounds of bark in 1882. In other words, we imported twice as much quinine and half as much bark in 1884, as in 1882.

As to opium, the next most important drug, it will probably astonish many readers to learn that in 1883 more opium was imported for smoking purposes (viz., 298,153 pounds) than for all other purposes put together, and that the money value of the opium imported for smoking in the past four years has on an average exceeded that for all other forms of opium. Last year there was a sudden and very great fall in the amount of opium imported for smoking, owing to a largely increased duty placed upon it.

GALVANO-PUNCTURE IN THE TREATMENT OF THORACIC ANEURISM

Dr. C. M. Richter reports (*Pacific Medical and Surgical Journal*) three new cases in which galvano-puncture was used in the treatment of aneurism. In one, a case of intra-thoracic aneurism, the patient is apparently cured (one year after operation). In the second, also a case of thoracic aneurism, the disease was very much advanced. Galvano-puncture was successfully performed, but, although it cured the aneurism, the patient died a month later. A post-mortem was made and a large saccular aneurism was found springing from the arch of the aorta. Dr. Richter says, as a result of this examination, that, "Thus, with the most unfavorable circumstances; with the highest degree of atheroma; with the sac as thin as tissue-paper, where the needles were inserted; with an aneurism of such dimensions; and all this on a decrepit individual—an entire cure of the aneurism and a perfect solidification of the sac was obtained by electrolysis."

The third case was that of a traumatic diffused aneurism of the radial artery; and here galvano-puncture failed.

Galvano-puncture for the treatment of aneurism has not yet obtained a position in surgical therapeutics. This is so true that even writers of the experience of Mr. Bryant, show an entire ignorance of the practical details of the operation.

Galvano-puncture, though introduced by an English surgeon—Phillips, in 1829—has been chiefly in the hands of the French surgeons and of the Italians. Among the latter, Civiselli reported 29 cases, with 11 "improvements," lasting over four years. Petit, in 1880, collected 114 cases, in 60 of which there was improvement. Barwell collects 8 cases, operated upon since 1877. Of these, 4 died, and 4 were improved. In the matter of technique, Barwell recommends the employment of both poles. Robin, Chambers, and Richter strongly insist upon using only the positive pole.

Chambers experimented on an imitation aneurism, and came with Robin to the same conclusion, that no clot is formed by the negative needle, while that of the positive is solid, resistant, and adherent. Both etherize the patient, insert several needles at the same séance, and let a strong galvanic current pass through them for from five to eight minutes per needle; they insist that the needle should be insulated, for instance, by collodion, and that about three centimetres of the polished steel of the needle should be exposed in the tumor.

RAILWAY HOSPITALS.

We learn from an article by Dr. C. B. Stemen in the *Fort Wayne Journal of the Medical Sciences*, that several western railroads have adopted systems providing medical and surgical care for their injured employees. The Missouri Pacific Railroad first started the plan of assessing a small monthly sum on all employees who receive fifty dollars a month or over, and a less sum on those receiving lower wages. The money thus collected constitutes a hospital fund, which is used in taking care of the sick and injured. This "provident plan" has been adopted by the W., St. Louis & P. Railroad, the St. Louis & Iron Mountain, and, we believe, by some other roads. A number of small hospitals have been erected, and in some cases the injured employees are obliged to go to these hospitals instead of going home.

The railway hospital system involves a great deal that is arbitrary, but on the whole it seems to have worked well and been of much service to the sick and injured.

IS DEATH NECESSARILY INSTANTANEOUS AFTER BULLET WOUND OF HEART?

A case of some interest has just been developed in a post-mortem examination held a few days since at Utica, upon the body of S. Clark Smith, killed by Dr. Richter at Middleville, N. Y., February 27th. It appeared that one bullet passed through the left auricle and right ventricle of the heart. Another ball passed through the right lung.

Each shot was fatal, but Smith walked by actual measurement eighty-two feet, before he fell. Upon the day when this murder was committed, Calvin McCarg was on trial at Utica for killing Theresa Johnson at Forestport last April, and the deed was committed in much the same way; but the expert testimony produced in the trial was strongly at variance with the facts as shown in the Smith case. Theresa Johnson was found dead on a bed in her father's house. In another room, twenty feet distant, a revolver was lying. One theory of the defence was suicide. This was rejected by the positive testimony of physicians that the girl's death was necessarily instantaneous, as the bullet passed through the right and left ventricles and aorta of the heart, and that she could not have stirred after receiving the fatal wound. Other physicians gave testimony disputing this conclusion, but the theory of instantaneous death was accepted by the jury and McCarg was convicted by circumstantial evidence.

After the conviction much interest was caused by the knowledge of the second murder and the demonstration it gave, that a person with two mortal wounds, one of which was similar to that of Miss Johnson, could move and did in fact walk eighty-two feet. The crime was satisfactorily proven against McCarg in any case, so that the doubt as to the correctness of the expert evidence would not make a new trial a necessary one.

DIET AND DYSPEPSIA.

One finds that, as in the name of liberty, so in that of common-sense, great sins are sometimes committed. And we can point to no greater recent instance than that of the article of the venerable Professor Austin Flint on the "Dietetic Treatment of Dyspepsia," read before the New York State Medical Association. The article in question has received wide circulation, and, as it appeals alluringly to "common-sense" and the "instincts" as against diet, drugs, and other artificial measures used for indigestion, we do not doubt that the doctrines inculcated will be adopted at once by many.

The special points in Dr. Flint's views which invite criticism are that dyspepsia is more or less a mental trouble, and that fixed rules of diet and established modes of life adopted to cure the dyspeptic tend rather to keep up the disease. Says the writer: "Don't diet yourself; don't systematize your meals; distrust your past experiences with foods that disagree; follow your instincts in gratifying your appetite. Learn a lesson from the *gourmet*, and fare sumptuously every day." Dr. Flint has never seen a dyspeptic cured by dieting.

Discussing these recommendations with chronic dyspeptics, we have been uniformly met with the statement that their author had not had and did not know dyspepsia. Probably nothing is more absolutely contradicted by experience than that dieting does not benefit, and does not sometimes cure dyspepsia. There is hardly a practising physician who has not evidence confirmatory of this. And the young doctor who, in the confidence of authoritative utterance, tells his dyspeptic patient, who is fond of pie, fond of sausage, flap-jacks, late suppers, and prodigious meals generally, that he can indulge his appetite and be guided by his instincts, will soon lose his case and gain wisdom.

Physicians will do well, however, to note the excellent advice which Dr. Flint gives, not to prescribe a line of treatment which unnecessarily concentrates the patient's mind upon himself and his stomach.

GENERAL GRANT.

At the time of our going to press General Grant is in a very feeble condition. His vital powers are beginning to give way, and his pulse is weak and intermittent. The local disease has evidently progressed, although this cannot be proved, owing to the physical impossibility of making a satisfactory examination of his throat. The exudation has not separated, and the sloughing process has extended to the free border of the palatal curtain on the right side. The gland under the angle of the right lower jaw has not enlarged, and the surrounding induration has in a measure disappeared. He is still able to walk from his bed to his chair. His nasal and pharyngeal passages are unobstructed, and his breathing, although somewhat labored, is unimpeded.

The present outlook is exceedingly grave. His liquid food, which he can generally swallow without pain, is amply sufficient for nourishment.

News of the Week.

The Texas State Medical Association holds its seventeenth annual meeting at Houston, beginning on Sunday, April 21st. Is Texas to introduce the European and un-Christian practice of holding medical conventions on Sunday?

A Histological Society has been organized in Austin, Texas.

The "Commercialization" of Medicine.—The correspondent of *L'Union Médicale* speaks of the relative attractiveness to students of Vienna and Berlin as medical centres. Vienna, he says, is now ahead. In Vienna, however, a large part of the "Docents" belong to the Israelitish race, and exhibit a tendency to indulge in the "commercialization" of medicine. The writer believes that, as a consequence, the tide of medical students will turn toward Berlin.

The Prospects for National Health Organization.—"The friends of a national health organization," says *The Sanitary Engineer*, "have reason to be satisfied with the appointment of Mr. Fairchild as Assistant Secretary of the Treasury in the place of Judge French. Mr. Fairchild has for a long time shown his active interest in health and social problems, having now for some time served as President of the State Charities Aid Association of this State, and not as a mere figurehead either."

The Association of American Medical Editors will hold its next annual meeting the evening before the day of the meeting of the American Medical Association. The following are the officers of the Editors' Association: President, Dr. Henry O. Marcy, Boston; Vice-President, Dr. John V. Shoemaker, Philadelphia; Secretary, Dr. H. O. Walker, Detroit.

The Prize for the Best Essay on the Prevention of Blindness, offered by the English Society for the Prevention of Blindness, has been awarded to a German physician, Dr. Fusch.

A Large Fee.—Koeberle, of Strasbourg, is said to have received a fee of 500,000 francs from a Spanish princess, whom he professionally attended.

Vienna Physicians.—The number of Vienna physicians is 1,500, in a city of 800,000 inhabitants. Vienna has therefore nearly as many proportionately as New York, and ten times as many proportionately as London, where there are 3,000 in a city of 4,000,000 inhabitants. The local journals complain of the hard times, the severe competition, and the small fees.

Cancer of the Tongue and Smoking.—Mr. Whitehouse writes to the *British Medical Journal*: "As to whether smoking may be the immediate cause of cancer, surgeons are not agreed; but there is a condition of the tongue which is, in many cases, the precursor of epithelioma, namely, 'leucoplakia;' and this disease is more generally considered to be caused by smoking. Mr. Barker, writing on this inflammation, in Holmes' 'System of Surgery,' points out that among 75 recorded cases, 71 smoked, and only 4 were non-smokers. Buzenet used the term '*plaques des fumeurs*' for this disease, because he was convinced that smoking so often gave rise to it. Mr. Hulke has more than once shown that 'leucoplakia' may be the starting-point of epithelioma, and out of the above mentioned 75 cases, 44 developed epithelioma, and in one only was there a family history of cancer." Mr. Morris also states that out of 55 cases of cancer of the tongue 13, or about one-fourth, had been the seat of this leucoplakia, or icthyosis. Mr. Bryant's experience has been of a similar character.

The Average Duration of Life in Cancer of the Tongue is, without operation, ten and a half months; with operation, sixteen months. In some cases, after operations, the patients have lived for from two to five years, or even ten years.

The Frequency of Cancer of the Tongue.—Five per cent. of all cancers are situated upon the tongue.

A New Medical Education Bill has been introduced into the State Assembly.

Medical Legislation in Minnesota.—"It is a matter of deep regret" says the *Northwestern Lancet*, "that the amendments to the medical registration act failed to pass. Now that so many States are passing medical laws or making their old laws more stringent, we need more protection against the crowds of charlatans who are being driven out from their old hunting-grounds. The history of the defeat of the amendments would, we imagine, be an interesting one to the profession, and we hope it will sooner or later be made public. In sanitary matters the Legislature has made 'the sanitary code of Minnesota the most complete, and the machinery for its execution the least expensive but the most simple of any State in the Union.'"

The Bacillus of Syphilis.—Dr. Lustgarten's researches are now finished and will be shortly published. He attributes real diagnostic value to the organism. In sixteen cases of syphilis he succeeded in rendering visible this bacillus by a mode of decolorization peculiar to itself. It is very similar to the tubercle bacillus, but always occupies a cell. In cases of sclerosis, gumma, and in the contents of syphilitic ulcers, the same micro-organism was found; in the soft chancre, however, the presence of a bacillus could not be proved.

Transmission of Tuberculosis by the Genital Tract.—M. Ricard adds another to the cases recently reported as illustrating the transmission of tuberculosis by the genito-urinary tract. A healthy man, aged twenty-three, without a tuberculous history, contracted a gonorrhœa. The discharge ceased in three months. Three months later he was attacked with cystitis, followed by pulmonary tuberculosis. Bacilli of tuberculosis were found in the urine.

Total Extirpation of the Uterus by the Vagina.—Dr. Max Schede, of Hamburg, has removed the entire uterus some dozen successive times with success, at his hospital in that city. Tait has removed the uterus fifty-four times, with nineteen deaths; Keith has done it thirty-eight times, with three deaths.

Mesmeric "Horses."—An *exposé* of the methods of travelling mesmerists was recently made in Chicago. One of the so-called subjects admitted that he made a business of being "mesmerized," and subjected to the ordinary tests of burning, pricking, etc. He was not, he said, really mesmerized, but acquired an insensibility simply by training. The same was true with his fellows, who were professional subjects. They simply trained themselves to stand the tests. They called themselves "horses." Every one who has seen these public exhibitions of mesmerism has observed that there was a great deal of trickery about them.

San Francisco.—According to the *Pacific Medical and Surgical Journal* the law of California regulating medical practice is a failure, because juries cannot be found who will convict, "even though they be the lowest Chinese charlatans." The San Francisco County Medical Society proposes to have a reading-room, but has to meet the following conclusive objections: "1, That of extra expense; 2, that the present library is not consulted; 3, that the present library is not worth consulting!"

Medical Missionaries Wanted.—A convention of medical students, physicians, and clergymen was recently held in Philadelphia, under the auspices of the Young Men's Christian Association. A number of addresses were made, Professors Parvin and Agnew being among the speakers. The object was the praiseworthy one of getting students interested in medical missionary work.

Collective Investigation in Germany.—The results of the attempt to obtain information by means of an organization similar to the Collective Investigation Committee of the British Medical Association, under the auspices of the Medical Society of Berlin, have been published, and they certainly show, says *The British Medical Journal*, that the medical practitioners of scientific Germany are, if anything, less easily aroused to participation in such work than their brethren in practical England. The inquiry, which extended over twelve months, related to certain points in the history of phthisis, and these have received separate reports. In all, two hundred replies were received, of which thirty-eight were useless. The first report is on the heredity of tuberculosis, by H. Vedendorff. The facts recorded are not specially striking, concerning, as they do, only 24 cases of phthisis. The second report, by Meyerhoff, is on the contagiousness of phthisis, and concerns 40 individuals, 23 of whom were husband or wife. Contagion appears to be most often communicated just before death. One case became phthisical after using the milk of a tuberculous cow. Leyden and Fraentzel report on the curability of phthisis, relying on fifty-seven replies. The greatest number were cured between the ages of twenty and thirty. In 9 cases both apices were affected. In 37 cases there was no special treatment, but the patients had been once or more to winter or other health resorts. Kalischer reports on 8 instances of pneumonia passing into phthisis. In 6 of the cases the pneumonia pursued a typical course.

Medicine in Florida.—The profession in Jacksonville is talented but reserved. There is no mixing. The County Society meets when it can get a quorum, which is very seldom. We have been cordially received by some, and not so cordially by others. Surgery has been greatly neglected in Florida. We found cases of stricture, small tumors, fistulæ, *et id omne genus*, sent to New York for treatment.—*Florida Correspondent of Southern Practitioner.*

A Curious Combination.—A Politzer air-bag and a Western medical journal are offered to subscribers for the small sum of two dollars.

Warm Discussions in the South.—The columns of some of our Southern contemporaries have been of late in a very heated condition. The warmth-centre started in Texas, where the *Courier-Record* chastised a Philadelphia professor for intimating that the mothers of Texas fed their babies with ensalivated and auto-peptonized crackers. A prairie-fire of resistless editorial logic consumed this slander. The heat-centre then passed to Atlanta, where the Hopkins-Hammond controversy engendered much fervid rhetoric. Richmond seems now to be the tropical spot, the occasion being the expulsion of a student from a medical college in that city. As to the sequel we quote the *Medical Age:* "The editor of one of our exchanges brands the dean of a certain medical college as 'one who has descended but little from his level and has reached the ranks of the lowest order of human depravity,' and posts him as 'a falsifier and slanderer, whose unscrupulous mendacity is only equalled by his asinine stupidity and close resemblance to the trembling spaniel.' One would naturally infer from this that our brother does not like the dean. Inasmuch as he says in a subsequent article, as a reason for rejecting a communication, that he 'will not print personal abuse of any man,' the average reader will be at a loss to know under what head he classifies the above. Perhaps it is a panegyric."

Mortality from Trephining.—Walsham deduced, from a study of 770 cases, the conclusion that the mortality from trephining was 10.6 per cent. R. W. Amidon, from a study of 125 cases operated upon since 1879, concludes that the mortality is only 3.2 per cent., provided symptoms endangering life have not already developed

The Westminster Hospital Medical School has recently begun the erection of a new building, which with the site is to cost about $75,000.

Our Esteemed Contemporary, the Philadelphia *Medical and Surgical Reporter*, criticises the *Medical News* for indulging in personal medical journalism, and sending a batch of confidential communications to the secular papers.

The Toledo Medical College, at its annual commencement, conferred degrees on thirteen students—eleven male and two female.

Fighting Quackery in Philadelphia.—At a recent meeting of the Philadelphia County Medical Society, efforts were initiated for carrying out the law against illegal practitioners. The committee having charge of the matter have made arrangements for dividing the city into sections, which will be placed under the care of one or more members of the committee, whose duty it shall be to search out and collect evidence against this class of practitioners.

The Market for Coca and Cocaine.—Coca leaves, writes Dr. Squibb, still continue to be very scarce and very high in price, both in this country and Europe, and those which are accessible are of very poor quality. The supply of cocaine is, however, considerable, and it can be manufactured and sold for thirty cents a grain, with a fair profit to the manufacturer.

The Indiana State Medical Society.—The meeting of the Indiana State Medical Society will be held in Indianapolis, convening the second Tuesday in May (12th), and closing on the 14th.

Dr. Henry B. Millard, of New York, has been recently elected, unanimously in each instance, a Foreign Corresponding Member of the Société d'Hydrologie Médicale, of Paris, and of the Verein Deutscher Aerzte, of Prague; in the latter particularly with reference to his researches in the department of the kidneys and urine. Dr. Millard is the first American elected to these societies.

Adulterations in Quinine.—As the result of investigations by the City Board of Health, one druggist has been arrested and two reprimanded for selling adulterated quinine pills. In one case the adulterations amounted to fifteen per cent., in another to about twenty per cent.

A New Bill for the Protection of Public Health.—Dr. Cartwright, of Delaware County, N. Y., has prepared a bill, which has passed the New York Assembly, for the purpose of adding safeguards against the introduction of cholera. The main features of the bill are indicated in Sections 1 and 6, which are as follows. It will be seen that these provide that all vessels bring a bill of health from all the ports at which they have stopped:

Section 1. It shall be the duty of the Health Officers at the several ports of entry within the State of New York, to require the masters of all merchant ships and vessels arriving at said ports from any foreign port to present a bill of health, duly executed by the Consul, Vice-consul, or other consular officer of the United States, or by the medical officer attached to the United States Consulate by appointment of the United States Government, or the representative of the United States Government resident at said port of departure, which shall set forth the sanitary condition and history of said vessel; also the sanitary condition of the cargo and of the crew and passengers; also the sanitary condition of the food, water, and ventilation of said vessel; the number of cases at such port of yellow fever, cholera, small-pox, typhus fever, relapsing fever, scarlatina, measles, and diphtheria; the total number of deaths from each of these diseases from all causes, the week preceding the date of said bill of health, as far as can be ascertained by the said Consul, Vice-consul, or other consular officer of the United States, or the medical officer attached to such consulate.

Sec. 6. The diseases against which maritime sanitary regulations at the port of New York shall apply are yellow fever, measles, cholera, typhus or ship fever, small-pox, scarlatina, diphtheria, relapsing fever, and any disease of a contagious, infectious, or pestilential character, which shall be considered by the Health Officer dangerous to the public health. And all such quarantinable diseases, except yellow fever, cholera, typhus fever, and small-pox, shall be removed to the emigration hospital, Castle Garden, or Ward's Island.

Sections 4 and 5 provide for examination as to vaccination, and vaccination if necessary.

The New Board of Health of the State of Maine.—Governor Robie has appointed the following State Board of Health: Frederick Gerrist, Portland; Lewis Barker, Bangor; Stephen J. Young, Brunswick; O. A. Horr, Lewiston; E. C. Jordan, Portland; and J. O. Webster, Augusta.

Dr. David Griffith, at one time one of the most prominent citizens of Louisville, Ky., died of paralysis on March 21st. He was the Medical Director of Sheridan's army corps, and was with General Nelson at the battle of Shiloh.

A Lipomatous Infant.—Accounts are published, apparently authentic, of an infant, aged thirteen months, weight eighty-three pounds, height about three feet. It is reported to be in good health and intelligent. This interesting monster lives in Norwalk, Conn.

The Prize-Ring.—Our esteemed contemporary, the *Sun*, states that the muscularity and general physical tone of the prize-ring was never at so high a pitch as at present, the various champions being superior to all their predecessors in any age. Thus we see the far-reaching effects of sanitary science.

The Birth-Rate of Illegitimates in Prague.—The city of Prague must have some special attractiveness for the erotic and the emancipated. Among 7,031 births there are 3,762 legitimate and 3,329 illegitimate; or per 1,000 persons, 43.12 births, 23.78 legitimate and 21.36 illegitimate. A curious fact is that the death-rate among the illegitimate does not greatly exceed that among the legitimate. The inhabitants of Prague evidently obey the injunction of Shakespeare: "Let copulation thrive."

A Serious Alphabetical Outlook.—*On dit* that Dr. Legaré Wistchnnewettzky, of Taganrog, Russia, the husband of Congressman W. D. Kelly's daughter (herself a physician) is to locate here, and give us one medical sesquipedalian.—*New York correspondent Virginia Medical Monthly.*

A Triumph for Experimental Science.—After a long and bitter fight, the Physiological School at Oxford is firmly established. In November, 1882, Professor Burdon-Sanderson was appointed Waynflete Professor of Physiology at Oxford. On June 5, 1883, the convocation voted by a majority of only three to appropriate $50,000 for the laboratory. On February 5, 1884, the vote was taken again on this point and the measure re-endorsed by a majority of forty-one. A final struggle was made by the anti-vivisectionists this spring upon the question of voting $2,500 for current expenses. A circular of protest was sent out, signed by Mr. Ruskin, Mr. Freeman, and several other professors and fellows. A counter-circular was immediately drawn up, and it secured a list of names still larger and more influential. The vote for the money was carried by a majority of 168 in a house of 656. "It is hard to over-estimate," said the circular issued by the anti-physiological party, "the influence on popular opinion which is exerted by the attitude of a University such as ours."

Death of Professor Von Frerichs.—We regret to announce the death, on March 14th, of Professor von Frerichs, of Berlin, in the sixty-seventh year of his age. Frerichs commenced his clinical and pathological studies at Breslau. He was called to Berlin in 1859, where he has been teaching ever since. He is best known for his treatise on diseases of the liver. He also wrote a work on Bright's disease, in which he enunciated the carbonate of ammonia theory of uræmia. Only last year he contributed a monograph on diabetes.

An Alleged Cure of Hydrophobia is reported in the *Lancet*. A native surgeon of India, Dr. Nursimula, treated the case with gr. $\frac{1}{16}$ of atropia. The patient was a man, aged twenty-four, who had been bitten by a dog the week before hydrophobia symptoms appeared.

Retirement of Professor Bouchardat.—Dr. Bouchardat, Professor of Hygiene at the Paris Faculty of Medicine, has, after a service of nearly forty years, retired, and his name is transferred to the list of Honorary Professors.

Dr. Frank Woodbury has been elected Professor of Materia Medica and Therapeutics in the Medico-Chirurgical College of Philadelphia.

The American Surgical Association holds its next annual session at Washington, D. C., on April 21, 22, 23, and 24, 1885. Ten papers and subjects for discussion are promised. The meetings will be held at the Army Medical Museum. Drs. Stephen Smith and J. W. S. Gouley represent New York.

The St. Louis Medical Colleges.—The medical schools of St. Louis closed their winter sessions the first week in March. The Missouri Medical College held its commencement Tuesday, March 3d, and conferred the degree of medicine upon ninety students. The St. Louis Medical College celebrated its commencement Friday, March 6th, graduating twenty. The St. Louis College of Physicians and Surgeons closed March 7th, and graduated eleven students.

Dr. Joseph Braman, of Braman's Corners, Montgomery County, N. Y., died March 25th, aged ninety-six. He was one of the oldest physicians in the State.

Reviews and Notices.

The Inhalation Treatment of Diseases of the Organs of Respiration, Including Consumption. By Arthur Hill Hassall, M.D., Member of the Royal College of Physicians, England, etc. Pp. 357. London: Longmans, Green & Co. 1885.

To the author belongs the credit of having produced the first English work upon this subject, and while making this statement he pays a handsome tribute to those of his French and American confrères who have preceded him in this therapeutic field. His experience has shown him the fallacies of some of the old theories on the subject, and the latter he has thoroughly recast. Experiments have demonstrated to him that our ordinary atomizers, nasal and oro-nasal inhalers, are practically useless so far as bringing medicated vapors in contact with the deeper air-passages is concerned. With the former the spray is nearly all condensed in the upper passages. The latter furnish very little inhalation, as nearly two-thirds of the medicament employed can be recovered after prolonged use of the inhaler. The essentials for true inhalation require primarily an increase of temperature over the surrounding atmosphere for complete volatilization, and a large surface from which the latter may take place. These two requisites our ordinary apparatus completely fails to furnish. Hence the employment of such therapeutic measures demands specially constructed chambers, or at least such devices as shall thoroughly charge with medicated vapor the air of an ordinary room. Such appliances, the author shows, can be easily prepared at small expense.

An interesting theory (credited to Sales Girons) is advanced, that the respiratory mucous membrane may serve as a channel for constitutional medication. The favorable conditions existing for this are the intimate relations between the blood and air in the lungs and trachea, and the fact that the blood can be charged with the vapor at the moment of its highest vitality. The author's experience includes the use, by inhalation, of some remedies rarely so exhibited on this side of the water, as, for instance, arsenic and digitalis. The final chapter discusses consumption, and regards as an open question our ability to destroy the bacilli by inhalation methods. It is shown, however, that the character of the secretions may be so changed as to greatly retard their development. The spirit of this most valuable treatise is that of a recognition of every plan of general treatment, to which inhalation is a most important adjuvant.

Women, Doctors, and Plumbers. By Mrs. H. M. Plunkett. Pp. 241. New York: D. Appleton & Co. 1885.

The aim of this book consists in showing that, "if women and plumbers do their whole sanitary duty, there will be comparatively little occasion for the services of doctors." Yet the medical profession is by no means relegated to the background. Its work as a pioneer in the march of sanitary science and preventive medicine receives its own due meed of praise. This manual is the warning of a housekeeper of many years' experience to her sisters, and yet the pages may furnish many revelations to medical men. The ideas set forth are within the comprehension of all.

They formulate into working theorems all the essentials of the domestic sanitary code. They tell us how to select a proper building site, and how to construct thereon a dwelling, in accordance with true sanitary law. We are warned against the vagaries of that modern triumvirate, the mason, builder, and plumber, and yet we are told that good work necessitates a fair outlay, that "cheap" houses generally mean poor health for their inmates. The style of the book is domestic and graceful. It ought to be on the shelves of every home library, and consulted even more frequently than the time-honored almanac or cook-book.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 11, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. T. MITCHELL PRUDDEN presented, in behalf of a candidate, a specimen illustrating *acute intestinal strangulation with gangrene from volvulus of the sigmoid flexure, with remarkable distention of the gut.*

DR. JOHN H. RIPLEY, in behalf of a candidate, presented specimens from a case of *diphtheritic tonsillitis, faucitis, and laryngitis tracheotomy, death.*

DR. R. C. SHULTZ, Acting Secretary, presented, in behalf of a candidate, *a fœtus strangulated by five loops of the cord encircling the neck.*

SUPPURATIVE INFLAMMATION OF THE TUNICA VAGINALIS TESTIS, FOLLOWING REPEATED TAPPING FOR HYDROCELE.

DR. T. M. PRUDDEN presented specimens of a case, for the clinical history of which he was indebted to Dr. W. F. Hazelton, House-Surgeon to Bellevue Hospital. S. M——, male, Cuban, aged forty-two, admitted to hospital February 6, 1885, with a scrotal tumor, which had the characters of a hydrocele, and was found, on the introduction of a hypodermic needle, to contain a clear amber fluid. Patient has had this for fifteen years. One week before admission it was tapped, and *probably* injected. After this patient was confined to a cold room, and had no food until he was brought to the hospital.

The sac rapidly refilled, and on admission was twenty inches in circumference. Patient is anæmic and emaciated. Temperature, 102½° F. Tumor is tense, red, and sensitive to touch. A few ounces of fluid were withdrawn, under the usual antiseptic precautions, to relieve the tension, and patient was put on tonics and extra diet in view of a radical operation. For six days after admission the temperature averaged 99° F. in the morning and 99½° F. in the evening. The evening rise was accompanied sometimes by slight chilliness, and invariably followed by sweating. On the seventh day, at night, temperature rose to 103½° F. Tumor was tapped and clear serum was withdrawn.

On the ninth day, at night, the temperature was 102½°: tapped, clear serum withdrawn. Following this the temperature ranged between 99° and 99½° F., with sweats following the evening rise till the eighteenth day from admission, when it fell to normal and remained so. Patient gradually emaciated and lost strength, having a typhoid tongue, diarrhœa, and occasional vomiting, and died on the thirtieth day after admission, apparently from exhaustion. No albumen or casts in urine.

At the autopsy Dr. Prudden found the heart normal; lungs moderately emphysematous, with chronic bronchitis; spleen small and fibrous; liver moderately fatty. The kidneys showed a moderate degree of chronic diffuse nephritis, being of about normal size, with adherent capsule, and thickened and roughened cortex.

The left tunica vaginalis testis was moderately distended, containing about one and a half ounce of clear yellow serum. The subcutaneous tissue on the right lower side of the scrotum was considerably thickened and dense. The sac of the tunica vaginalis on the right side was much distended and very tense, and contained about one pint of odorless pus, in which floated numerous yellowish shreds of apparently dense masses of pus. The inner surface of the sac was partially lined with an irregular membranous layer of fibrin and pus. The testicle was crowded back and flattened to a mass about half an inch thick.

A portion of this pus was received into a clean bottle and was examined microscopically, as well as a portion of the cyst-wall with its lining purulent pellicle. The pus was fairly swarming with bacteria of two kinds: those which are so frequently found in connection with the suppurative process in various parts of the body, namely, the *staphylococcus pyogenes* and the *streplococcus pyogenes.*

These cocci, specimens of which are shown under the microscopes, have been fully described by Ogston, Rosenbach, Passet, and others, and need not be described here further than to say that the staphylococcus, of which there are several varieties, has the form of minute spheroidal bodies, which may occur singly or in clusters, while the streplococcus is apt to occur in longer and shorter chains.

These cocci have been separated by pure culture and found to induce suppuration by inoculation in animals. Microscopical examination shows that the purulent pellicle which lined the distended sac contains enormous numbers of the cocci, singly and in larger and smaller masses. These are shown under the second microscope.

DR. JOHN C. PETERS inquired whether the hydrocele was tapped with a large trocar.

DR. PRUDDEN replied that the tapping, while the patient was in the hospital, was performed with the hypodermic needle. The exact nature of the operation performed previous to that time was uncertain; it was possible that some material was injected after the withdrawal of the fluid.

DR. PETERS added that his object in asking the question was to learn how the bacteria or cocci got into the tunica vaginalis.

DR. PRUDDEN said that suppuration did not take place until after the tapping with the hypodermic needle, about twenty days before the patient's death. He coincided in a remark by the President, that a mechanical source of invasion was not necessary for the development of cocci, as they were found in deep abscesses which had no apparent communication with the exterior. Dr. Prudden also referred to their presence in dish-water, etc., and their possible relation to the sore hands of housemaids.

THE PRESIDENT said that the case related by Dr. Prudden was not unique with respect to death from tapping a simple hydrocele with a hypodermic needle, as several such cases were on record.

HYPERPLASTIC ENLARGEMENT OF THE OVARIES.

DR. H. C. COE presented several ovaries, which were interesting because of their power apparently of performing their function as well as in health, notwithstanding the fact that they had undergone marked enlargement. The specimens led to the inference that in a great many cases diagnosis of useless ovaries was made by the operator rather than by the pathologist. He had as many as thirty or forty enlarged ovaries in his possession which on close examination revealed normal Graafian follicles, and had been, as far as appearances went, useful organs. They resembled very closely true fibroid tumor, and under the microscope it was difficult to distinguish between their structure and that of a real fibroid. In the few cases of so-called fibroid tumor of the ovary which he had seen, it was impossible to avoid the inference that the change was simply a hyperplastic increase of the ovarian stroma, and that they did not constitute real tumors.

One of the specimens illustrated hæmatoma of the ovary, or hemorrhage into what was originally a Graafian follicle or small cyst. In the centre of one of the ovaries was a number of small cysts, the walls of which were very much thickened. This had been spoken of as a possible explanation of the development of cystic ovaries; *i.e.*, a small cyst became imprisoned within the centre of the ovary, surrounded by fibroid tissue, and being unable to reach the surface, developed within the interior of the organ. Dr. Coe had sometimes entertained the idea, although it might be fanciful, that the pain which some patients experienced at menstruation was due to the difficulty with which the follicles burst through a thickened capsule.

DR. PRUDDEN asked Dr. Coe concerning the degree

of thickness of the capsule necessary to cause difficulty in the rupture of the Graafian follicle.

Dr. Coe replied that according to his observations the ovarian cortex presented varying degrees of thickening at different points; at some points it was so thick that probably rupture of the follicle was aborted.

Dr. Ripley inquired, with regard to the first specimen presented by Dr. Coe, whether menstruation was abnormal.

Dr. Coe replied that he did not remember the history of each case, but in most of them there was severe dysmenorrhœa.

Dr. Ripley said his object in asking the question was to learn whether this change in the ovary might not exist without the presence of dysmenorrhœa. Even if dysmenorrhœa were present, it would not necessarily be due to the cause mentioned by Dr. Coe.

Dr. Coe remarked that a number of cases of disease of the ovary had been observed at autopsy, there having been no history of ovarian trouble during life.

Dr. H. J. Boldt inquired whether the ovaries had not become prolapsed, which condition in itself would give rise to dysmenorrhœa.

Dr. Coe said that as a rule enlarged ovaries which had not become adherent in their normal position from inflammatory adhesions, sank below their usual level.

Dr. Boldt's observations confirmed that statement.

Dr. W. P. Northrup asked if it was considered that menstruation and ovulation were contemporaneous.

Dr. Coe thought it was fair to suppose that there was some connection between the two. Theoretically we might suppose that in health the Graafian follicle ruptured prior to menstruation, whereas in disease rupture occurred later.

The President thought a death-blow to the argument was that menstruation sometimes continued after removal of the ovaries.

Dr. Coe thought it a question whether the discharge which sometimes took place after ovariotomy was true menstruation.

The President mentioned the fact that at the meeting of the Medical Society of the State of Georgia two cases were referred to by gentlemen of high authority, in which the women conceived after complete removal of both ovaries.

Dr. Ferguson thought there was a possible source of error in these cases, for he had several times found elongation of the ovary to two and a half to three and a half inches. In such a case the operator might remove only a portion of the organ and suppose that he had removed it entirely.

Dr. Coe remarked that he had found a mass of old adhesions which had exactly the gross appearance of an ovary, and afterward found the true ovary (which was atrophied) almost by accident.

AMPUTATION OF THE HAND.

Dr. Van Gieson presented the hand of a man, aged about thirty years, a painter by occupation, which had been removed for an injury sustained by the fall of the paint-pot of his fellow-workman who was on the ladder above him. The edge of the pot struck upon the metacarpus, while the hand was resting upon the round of the ladder. The patient was treated for some weeks by his family physician, and finally entered St. Catherine's Hospital. As he was anxious to retain the hand, the surgeon in charge gave him every opportunity to do so, but in spite of the opening of sinuses, and washing the parts with disinfectant solutions, the case went from bad to worse, dead bone could be felt wherever the probe entered a sinus, and the patient then became anxious for amputation. A careful examination of the member led the surgeon to the conclusion that it was better to comply with the patient's wish for amputation than to try to save the hand by an operation of exsection. The appearance of the parts after removal made it evident that exsection would not have been wise, as in all probability it would have been followed by amputation. The articulating heads of the radius and two of the metacarpal bones were destroyed in the necrotic process. Dr. Van Gieson remarked that in some cases on record in which the indications seemed to have been favorable for excision, the final result showed that amputation would have been preferable, and this was especially true when the disease had become somewhat extensive.

SARCOMA OF THE LUNG.

Dr. Van Gieson presented the lungs, the seat of sarcoma, removed from the body of a man twenty-seven years of age, who about fifteen months ago, when examined by his physician, was found to have some dulness over the apex of the right lung, the limits of which seemed to be well marked; and there was some enlargement of the glands of the neck. The diagnosis made at that time was incipient tuberculosis, with involvement of the glands of the neck. The patient passed from under the observation of the physician for a year, when he again came under his care in the hospital. Dr. Van Gieson saw him a few minutes after he entered the hospital, when he was suffering from intense dyspnœa, and a satisfactory physical examination could not then be made. The next morning there was found to be universal dulness over the right lung, less pronounced dulness upon the left side, the glands of the neck and those in the axillary space were very much enlarged, and there was a marked prominence of the middle of the sternum. The patient died of exhaustion ten days after admission.

At the post-mortem, made seven hours after death, the following notes were taken by the pathologist: The body was very much emaciated; there was general anasarca; sarcoma of the right lung; enlargement of the axillary and cervical glands; the thorax contained eight pints of serum; the spleen was found filled with nodules; the liver was not involved; the left kidney contained a white infarction; the retroperitoneal and the lumbar glands were involved to a very great extent; the intestines were in a normal condition.

CARCINOMA OF THE PERITONEUM.

Dr. Van Gieson exhibited a second specimen of malignant disease, that of carcinoma of the peritoneum, removed from the body of a man who died in his fiftieth year. Some time before his admission to St. Catherine's Hospital the patient had had the great toe amputated by Dr. Markoe, in Bellevue Hospital, for a disease which was thought to be of a semi-malignant character. The only symptom which seemed to be of special importance on his admission to St. Catherine's Hospital, November, 1884, was an enormous abdominal enlargement in the region of the spleen, extending to the right side and downward to near the suprâpubic region. Over this region the percussion note was dull. The surface of the tumor was smooth, and it seemed as if the mass could be lifted up. There was apparently a sharply defined border. The patient was excessively anæmic, the conjunctivæ almost bloodless. Microscopic examination by the pathologist to the hospital seemed to indicate an excess of white blood-corpuscles, but means for an exact estimate of their number were not at hand. The patient's appetite was good, he suffered no pain, and there was no nausea except a few hours before death. Dr. Van Gieson had examined the patient carefully on several occasions, and had made a diagnosis of splenic leucocythæmia. He based his diagnosis upon the fact that there was freedom from pain, freedom from nausea; there was desire for food, intense anæmia, and the microscopic examination of the blood seemed to point to leucocythæmia. The necropsy revealed extensive carcinomatous degeneration of the peritoneum and mesentery. In certain portions, especially in the region of the sigmoid flexure, the gelatinous form of degeneration was found, which probably would eventually have resulted in colloid degeneration, which was present elsewhere. He was not prepared to say, however, whether carcinoma of

the peritoneum was initially a form of so-called colloid cancer. The point in the case which especially interested Dr. Van Gieson related to diagnosis. He had seen, and been able to verify, in private practice, six cases of malignant disease of the peritoneum, in all of which there were marked emaciation, pain, and occasional nausea. But in the present case all of these symptoms were absent, the body was fairly nourished, the patient was free from pain, and nausea was absent. One of the physicians who saw the patient suspected a possible connection between the abdominal trouble and the former disease of the toe.

In the case of sarcoma of the lung there was marked emaciation, it differing in that respect from four or five cases previously seen by Dr. Van Gieson, in which emaciation was not a marked symptom.

Dr. A. G. Gerster inquired, concerning the first case, what was the character of the inflammation of the hand, whether phlegmonous, septic, or one of the forms of inflammation called tubercular?

Dr. Van Gieson replied that the question of tubercular inflammation was raised, but there were no physical signs of tuberculosis of the lungs, and when he saw the patient nine weeks ago his appearance was that of excellent health.

Dr. Gerster remarked that if the extensive destruction of the bones of the hand were due to phlegmonous inflammation, exsection certainly would not have been indicated. But if it were due to tuberculosis, exsection would have promised a better result, especially if the soft parts were not extensively implicated. He thought the fact that the patient rapidly recovered health after amputation was not against the possibility of the disease having been tubercular; for it was usual for patients, after being relieved of a source of suppuration, to rapidly improve in general condition.

Dr. Ferguson inquired whether the lung, the seat of sarcoma, had been examined microscopically.

Dr. Van Gieson replied that he hoped to be able to report the microscopical examination soon, but that the diagnosis at present rested upon the gross appearances.

He asked Dr. Prudden whether so-called colloid cancer of the peritoneum was initially carcinoma, the gelatinous appearance developing later.

Dr. Prudden said that question had frequently been raised, and he had come to the conclusion, after examining a considerable number of specimens, that both things occurred; that in some cases the disease was in the beginning colloid, while in others it began as a carcinoma, and later took on colloid appearances. As to the relative frequency of the two conditions he could not speak.

Dr. Van Gieson remarked that the two processes seemed to be present in different portions of the peritoneal cavity in this case.

Dr. R. W. Amidon asked Dr. Van Gieson if in the cases in which there was absence of pain the neoplastic process had not yet involved the serous membrane. In a case of colloid cancer of the peritoneum, the specimen from which he presented five or six years ago, and in which pain was a very prominent symptom, both the visceral and the parietal layers had become much involved by the disease.

Dr. Van Gieson was of the impression that in all of his cases both the visceral and parietal layers were involved; they evidently were so in the specimen presented.

Dr. Gerster asked whether the condition of the retroperitoneal and inguinal glands would not throw some light on the diagnosis.

Dr. Van Gieson replied that the inguinal glands were not enlarged.

Dr. Coe remarked, with reference to the condition of the blood in leucocythæmia, that in four or five cases in which he had examined it under the microscope, it was evident at a glance that leucocythæmia was present.

UTERINE FIBROID AND COLLOID DEGENERATION OF THE OVARY.

Dr. John C. Peters related the history of a colored woman, nearly seventy years of age, who came under his care three months prior to death. She had been supposed to have malarial attacks, for which she had taken quinine and various other remedies. There was ascites, albuminuria, diarrhœa, delicate appetite, absence of pain. Malignant disease was suspected, and also the possibility of fibroid of the uterus, usually present in colored women. The liver and spleen were not enlarged. Death took place from exhaustion.

The autopsy was made by Dr. Ferguson, who presented the specimens, and stated that the interest of the case centred in the fact that there were two varieties of growth present, one being a soft fibroma of considerable size involving the body of the uterus, and the other a colloid cancer of the right ovary, and secondary nodules in the peritoneum. There was a large amount of fluid in the peritoneal cavity. The heart was small.

Dr. Peters remarked that last summer the patient was in apparent good health.

GENERAL MILIARY TUBERCULOSIS.

Dr. Van Santvoord presented the lungs of a child which died at the age of nine months, having had general miliary tuberculosis. The specimen was chiefly interesting because of the extensive involvement of the lung in a patient so young.

CIRRHOSIS OF THE LIVER—CHRONIC DIFFUSE INTERSTITIAL NEPHRITIS—GLYCOSURIA.

Dr. W. P. Northrup presented a specimen accompanied by the following history:

The patient was Mrs. A——, aged sixty-two, a native of this State, and resident of this city; a total abstainer from the use of alcohol; without hereditary taint of any kind; a woman of strong physique; clear, florid complexion, and excellent health until a year before her death.

In May, 1884, she began to fail in general health, began to lose flesh; complexion became sallow; had fugitive pains; "neuralgia" of left side of head, left arm, and leg. This general condition prevailed till September, 1884, then she became deeply jaundiced, and so remained for six weeks. From that time the jaundice of conjunctivæ and skin gradually disappeared. The skin, however, maintained the dirty brownish color characteristic of the liver lesion. The fæces were at first pasty and clay-colored (looked like putty), became later rather more yellow and dry and "crumbly." The patient remembered that her ankles had been inclined to swell for two years.

November 1, 1884, the abdomen, which, from loss of fat in a previously rather corpulent person, was flaccid, became gradually distended with fluid. General anasarca followed ascites. A few days before death the abdomen was relieved by trocar of seventeen quarts of clear, straw-colored fluid. It is somewhat difficult to determine the quantity of urine passed. Dr. Northrup's acquaintance with the case began about four months before the death of the patient. At that time ascites was pronounced, the quantity of urine passed was sixteen ounces in twenty-four hours. There was a history of frequent and copious micturition for months before the patient really became sick. This was thought to be due to excessive use of Saratoga mineral waters.

Four months before death the urine was examined and found to be slightly bile-stained, having a "sickish," sweet, "heavy" odor; strongly acid; specific gravity, 1.023; a trace of albumen (thought to be due to pus from vaginal discharge); sugar, three to four per cent.; pus, amorphous waters, no casts; quantity, sixteen ounces. Examination a week later: Quantity the same, sugar the same, specific gravity, 1.012.

Gradually the sugar decreased in quantity, and wholly

disappeared three weeks before death; specific gravity ranged from 1.012 to 1.023; albumen disappeared; no casts; quantity decreasing; fæces remaining dry, hard, and lemon-yellow, and passed in large irregular masses. Pulse remained full and strong till the last two days, and one day after coma set in—80 a minute.

Patient died in coma.

Autopsy.—Heart: moderate hypertrophy of left ventricle. Liver: Size, that of the liver of a four-year-old child; color, grayish; consistence, hard and unyielding; surface, granular and nodular. On section, color yellow (cirrhotic), mottled with red. The section under the microscope shows the characteristic lesions of chronic diffuse interstitial hepatitis, with added parenchymatous degeneration. Spleen normal in size and consistence. Kidneys normal in size, hard and unyielding; capsule strips off, tearing away the kidney at points of adhesion; surface of the organ lobulated. On section the markings of cortex are indistinct and pale, pyramids congested. The specimen under the microscope shows an interesting example of chronic diffuse interstitial nephritis with parenchymatous degeneration. The walls of the blood-vessels are thickened; walls of the capsules are thickened; in many places the vascular tufts are crowded into small quarters by this thickening, and many are wholly transformed into connective tissue. There is also degeneration of the epithelium of the convoluted tubules. No casts in tubules. Colon filled with irregular masses of yellowish-gray fæces. These when crushed are granular and dry. Mucous membrane of intestines normal.

Remarks.—We have, then, a case of (1) ordinary cirrhosis of the liver in a person of abstemious habits; (2) chronic Bright's disease; (3) organic disease of the liver and kidneys attended with glycosuria. The glycosuria was not attended by any other symptom of diabetes mellitus. It seems of interest on account of the amount of sugar present, and that it completely disappeared before death.

I found the friends of my patient imbued with the idea that "in dropsy tapping is a last resort." In view of the necessarily grave prognosis in the case, I advised the operation, but did not urge it. Then came a time when the patient asked for any relief, and herself suggested tapping. So great was the œdema of the subcutaneous tissue that the wound made by the trocar did not close, and the patient had the annoyance of being more or less wet all the time.

After the fluid was removed the patient complained of pain over the region of the liver and along the spine, which was not relieved by a tight, many-tailed bandage nor lying in bed, and by no means all the fluid had been removed.

The tapping proved to be a "last resort," for the patient in two days passed into coma, and died three days later.

In looking back I am convinced that had the patient been tapped earlier the kidneys would have had a better opportunity to do their work, all the abdominal circulation would have been facilitated, and the wound of the abdominal wall would have closed promptly.

Dr. Ripley remarked that the size of the liver alone would not point to atrophy, inasmuch as the normal liver in the adult varied in weight from a pound to five or six pounds. Another interesting fact was that the liver decreased in size after the fiftieth or sixtieth year. Further, cirrhosis of the liver might occur without the abuse of either food or drink, and in the absence of syphilis.

SECTION OF SARCOMA OF THE BRAIN.

Dr. Ferguson presented under the microscope a section of the sarcomatous tumor of the brain exhibited at the last meeting.

REPORT OF THE COMMITTEE ON MICROSCOPY.

Dr. Ferguson also reported on the specimens presented by Dr. Van Santvoord at the last meeting of the Society, that the ulcer of the epiglottis and the disease of the bones were tubercular in character and contained large numbers of tubercle bacilli.

The Society then went into executive session.

[Note.—Dr. John C. Peters, Editor, stated that a sufficient number of copies of The Medical Record could be obtained from the library of the New York Academy of Medicine, in exchange for books, to make complete scrap-book volumes of the proceedings of the Society from the year 1866 to the present date. He asked the members to aid him in securing these complete volumes by sending books to be exchanged for medical journals.]

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, February 26, 1885.

Alexander S. Hunter, M.D., Chairman.

Dr. Henry E. Crampton read a paper on

INVERSION OF THE UTERUS,

in which he gave the history of the following case: Mrs. L——, twenty-eight years of age, had borne one child, had had one abortion, and at her second confinement was the subject of the accident which formed the basis of the paper. She was delivered with forceps. Otherwise there was nothing special in the history of the labor. When Dr. Crampton visited her for the second time, twenty-six hours after confinement, he found the patient doing well. Five hours afterward, that is, thirty-one hours after the completion of labor, he was called in haste, and when he arrived he found the patient in quite a restless condition, and on examination found the uterus completly inverted. With the aid of Dr. A. S. Hunter, who assisted him in delivering the woman with instruments, and Dr. W. T. Lusk added to the council, the uterus was, with very great difficulty, reposited thirty-eight hours after confinement. The woman died forty-four hours after delivery, from shock and hemorrhage.

Dr. Crampton then reviewed the literature of the subject, referring especially to the notable monograph written by Cross, who collected the largest number of cases, and made a complete *résumé* down to the year 1850. He had been able to collect two hundred and ten cases of complete uterine inversion following parturition, occurring or treated since 1850. From a study and analysis of these he reached the following conclusions:

1. Inversion of the uterus is preceded by paresis of some portion of the uterine muscle (not necessarily of the placental site) caused either by too frequent childbearing, tedious labor, previous miscarriages, traumatism (blows upon the abdomen received during pregnancy or labor). emotional excitement (notably in primiparæ), or too rapid labor. It is a pure neurosis in its inception. Traction upon the cord induces prolapse, or if severe, procidentia. It will *never alone* produce inversion, but may facilitate it if paresis is present.

2. It is more apt to occur in first than in subsequent deliveries.

3. This liability in primiparæ is due to the peculiar emotional excitement preceding and associated with a first labor, reflected upon the exhausted uterine muscles for the first time called into unusual action (eight in ten of all cases of puerperal eclampsia occur in primiparæ for analogous reasons). Given a slight degree of depression, and the natural vigorous contractions of the uterus in a first labor become a source of increased danger.

4. In the great majority of cases of recent inversion, firm and persistent pressure (under anæsthesia) upon any portion of the inverted organ will serve to reposit it.

5. In chronic inversion gentle, graduated, and long-continued pressure, either manual or instrumental, or both combined, has proved the most successful treatment.

Forcible taxis is not devoid of danger. Extirpation is a last resort.

6. Chronic inversion would be rarely found if every physician adopted the invariable custom of making repeated and careful vaginal examinations within twenty-four hours after every labor.

7. The prophylactic treatment of uterine inversion is obviously the same as that required for the prevention of puerperal eclampsia.

Dr. Malcolm McLean referred to a case which occurred in the practice of Dr. John B. Campbell. Mrs. ——, twenty-five years of age, primipara, a previously strong and healthy woman, went through a normal pregnancy. The first stage of labor was of eighteen hours duration. The second stage was completed, without assistance, in two hours and a half. Chloroform was administered in the second stage. The third stage of labor was accomplished in fifteen minutes, the uterus contracting firmly and promptly, although it seemed at times to soften up for a moment or so. The doctor did not leave the patient, however, until uterine contraction was firm, and could be distinctly felt. Two hours afterward the uterus was found completely inverted, and almost distending the vulva. It was reposited with considerable difficulty, but quite promptly. Four days afterward the woman was taken with chill, septicæmia developed, and she died on the fifteenth day. Dr. McLean spoke specially of the sensation which the inverted uterus gave to touch, namely, as if pressing upon a piece of wet chamois; there seemed to be complete paralysis of the organ. Dr. McLean also thought that absolute gravitation of the abdominal viscera had considerable to do with the production of this accident.

Dr. J. P. Garrish had just completed his five thousandth case of labor in private practice, and in these he had seen only four cases of inversion of the uterus, all of which occurred in patients who were being attended by midwives. His method of reposition had been to place the woman upon her hands and knees and, holding a ball of medium size in the hand, to press against the protruding mass firmly and steadily, and in all the cases which he had met the reposition had been effected quite promptly. To arrest the hemorrhage in these cases, the most effectual agent he had employed had been vinegar, carried into the uterine cavity on a saturated mass of cotton.

Dr. Boldt referred especially to the manner of removing the placenta with a view to prevention of inversion of the uterus. He objected to the frequent vaginal examinations after confinement recommended by the author of the paper.

Dr. Kearney spoke of the difficulties which sometimes arise in making a differential diagnosis. He was of the opinion that, in all cases of inversion of the uterus, paresis of the organ existed, and was inclined to think that the accident was never caused by traction on the cord. He also objected to the frequent vaginal examinations suggested by the author of the paper for the purpose of diagnosis after confinement.

The Chairman also agreed with Drs. Kearney and Boldt with reference to the frequent digital examinations after labor, and thought such examinations justifiable only in case of failure to determine whether or not this condition of affairs existed.

Dr. Crampton, in closing the discussion, said that he spoke of making vaginal examinations within the first twenty-four hours, and he still thought that it was not inadvisable, and that they could be made with safety to the patient if proper precautions were taken. The principal points to which he wished to direct attention were paresis in the etiology of inversion of the uterus, and the emotional disturbances of the primipara, and of frequent child-bearing in the multipara, as a cause of this paresis.

The Chairman gave notice that at the stated meeting in March, Dr. Malcolm McLean would read a paper on "An Improved Method by which to Complete the First Stage of Labor in Placenta Prævia."

The Section then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ABDOMINAL SECTION FOR ACUTE PERITONITIS—PAPERS ON THE SUBJECT BY MESSRS. TREVES AND MARSH AT THE MEDICO-CHIRURGICAL SOCIETY—THE ANTI-VIVISECTIONISTS AGAIN—UNIVERSITY DEGREES FOR LONDON MEDICAL STUDENTS.

London, March 14, 1885.

Abdominal section for acute peritonitis! This is sufficiently venturesome a proceeding, one would think, to satisfy any surgeon, however enterprising. Yet it has been recently performed by two different surgeons, and in each case with success. In one, the operator was Mr. Frederick Treves, Surgeon to the London Hospital; the surgeon in the other was Mr. Howard Marsh, of St. Bartholomew's Hospital. The cases formed the basis of two papers by these gentlemen at the last meeting of the Medical and Chirurgical Society, the reading of which excited a good deal of interest, as might be expected, and was followed by a lively discussion.

Both these gentlemen are well known in the surgical world, and as they both took prominent parts in the meetings of the Surgical Section of the Congress in London (1881), will probably be remembered by those Americans who were present.

Mr. Treves, although quite a young man, is well known as a bold surgeon. He has the reputation at his hospital of being unsparing in the use of the knife when a resort to it is necessary. Last year he brought forward at the same society what he termed "The Direct Treatment of Spinal Caries." His paper excited great interest at the time, and was followed by a discussion which lasted the entire evening. Although not the first to perform the operation, Mr. Treves did good service by drawing attention to it, and his successes have induced other surgeons to follow up the subject, and in some instances with marked success. I described Mr. Treves' operation at the time (January, 1884), and therefore need not dwell upon the subject further now.

In his present paper, Mr. Treves narrated the case of a young woman, twenty-one years of age, who came into the London Hospital on January 21st. She was then suffering from chronic pelvic peritonitis, following severe gonorrhœa. On February 25th symptoms of acute diffuse peritonitis suddenly appeared. On the 26th, the patient being in a very critical condition, the abdomen was opened, with antiseptic precautions. The general surface of the peritoneum showed the ordinary appearance of acute peritonitis. The intestines were lightly glued together in some places. A quantity of semi-opaque fluid, mixed with lymph-flakes and pus, escaped. The whole peritoneal cavity was well washed out with water, and a drainage-tube introduced. The patient was allowed to go in the hospital garden on the fortieth day. Mr. Treves alluded to several cases in which operations involving laparotomy had been performed successfully during the progress of acute peritonitis, the cases having been in most instances the subject of error in diagnosis. He also referred to the recent experiments on dogs by Dr. Parkes, of Chicago. In conclusion, he suggested the performance of abdominal section in certain cases of acute general peritonitis, such as that following injury, gunshot wound, the bursting of an abscess, and some forms of perforation.

Mr. Howard Marsh's case was one of acute circumscribed suppuration of the peritoneum, occurring in a youth of nineteen. He performed abdominal section and washed out the cavity with a one in sixty solution of carbolic acid, by means of a soft india-rubber catheter. The patient rallied somewhat at the end of four hours, the temperature being normal. The wound healed in twelve weeks, but the bowels never acted without enemata. Dr. Andrew and Mr. Marsh thought that the case might be

one in which an abscess in the mesentery around old tubercular glands had burst. The disease was so extensive that it could hardly be regarded as an ordinary circumscribed peritonitis. Mr. Marsh said he thought that in cases where there was any definite collection of pus in the peritoneum, the abscess should be opened and freely drained. He did not think the operation would be attended with any large measure of success in cases of suppuration of the whole peritoneum, because of the extensive surface involved and of the difficulty of drainage afterward. The formation of extensive adhesions might also cause obstruction of the bowels.

In the discussion which ensued, the President (Dr. George Johnson) remarked that it was plain that the life of each patient had been saved by the surgical procedure adopted.

Mr. Bryant warmly commended Mr. Treves, and said the value of his paper was enhanced in that it advocated the application of well-recognized surgical principles to the treatment of abdominal abscesses. He thought Mr. Treves might have brought forward cases from other sources to prove the correctness of his views, such as, for example, cases of abscesses about the cæcum, which, as Mr. Treves had shown in his demonstration at the College of Surgeons, were really abscesses of the peritoneum, for there was no portion of the cæcum that was not surrounded by peritoneum. Mr. Knowsley Thornton, Dr. Douglas Powell, Mr. Barwell, Dr. Goodhart, and Mr. Meredith also took part in the discussion. After a few remarks from Dr. George Johnson, Mr. Treves and Mr. Marsh briefly replied.

The anti-vivisectionists sustained another defeat at Oxford on Tuesday last. The occasion was the bringing before Convocation of a decree to grant £500 annually for the maintenance of the new physiological laboratories which cost ten thousand pounds. The clerical party strained every nerve but were outvoted, 412 voting for the decree as against 224 against it.

A meeting of the Metropolitan Counties Branch of the British Medical Association was held yesterday week, to consider the subject of university degrees for London medical students and the report of the council of the Branch on the subject. A lengthy discussion followed and an important speech was made by Dr. Bristowe, in which he recapitulated the more important of the points dwelt on in his former letter on the subject to the Chancellor of the University, Earl Granville, now Foreign Minister. I have several times referred to this subject and only briefly allude to it now to show the continued interest it is exciting.

"THE TRUE POISON IN THE COFFEE-CUP."

To the Editor of The Medical Record.

Sir: In the issue of your valuable journal dated February 14th, in a letter entitled "The True Poison in the Coffee-Cup," a correspondent makes two assertions which may mislead some of your readers. The first was that the Board of Health "was making a mountain out of a mole-hill" when it claimed that the material used to give coffee a bright green color contained enough poison to make the so-called coffee injurious. The second was that a much greater evil is being carried on without the interference of the health officers in the sale of what is known in the trade parlance as "poor skimmings."

The process of coloring and polishing coffee, to which your correspondent refers, was objected to by the Board of Health because poisonous pigments were used. The green color was produced by revolving the coffee in large boiler-iron cylinders with a mixture of prussian blue and chrome yellow (lead chromate). The shade of green was brought to any desired tint by the addition of one or more of the following colors: Burnt umber, yellow ochre, drop black, and venetian red. The process was finished by adding powdered soapstone and gum arabic for the purpose of giving the berry a fine glazed polish. It is impossible to impart color to an article of food or drink by means of lead chromate without introducing enough lead to render the article unsafe for human consumption. Burnt umber, yellow ochre, and venetian red are all liable to be contaminated with arsenic. In one sample of coffee which had been treated with yellow ochre, Dr. Waller the chemist of the Health Department, found the equivalent of $\frac{1}{60}$ of a grain of arsenite of copper in a half ounce of coffee, the quantity necessary to make a cup of the beverage.

The coloring and polishing of coffee has not been stopped, but the use of poisonous colors for that purpose has been prohibited. The green color now used is a mixture of indigo and turmeric.

Chrome yellow is a favorite color with manufacturers of food. I have found it in candy, mustard, vermicelli, and cake. In the two latter articles it was used instead of eggs.

Lead pipes have contaminated drinking-water; lead has been found in preserves put up in open cans made from "lead tin plate." It has also been found in food cooked in utensils made from "lead tin plate." These articles of food might be all eaten at one meal, followed by a cup of leaded coffee. I consider it one of the first duties of a Board of Health to stop the free use of this insidious poison in connection with human food.

The second assertion can be disposed of in a very few words. Before being used, coffee must be subjected to the process of roasting; it must be subjected to a very high degree of heat (about 320° F.) for about forty-five minutes. Now I may be wrong; if I am, I would like to know it; but it is my opinion that this degree of heat applied for the length of time stated, will destroy any injurious mould or rot that may be present in the substance.

The traffic in skimmings should be stopped, for it cheats the poor; but I do not believe it can be attacked from a sanitary standpoint.

I am very respectfully yours,

Cyrus Edson, M.D.

50 West Ninth Street, February 16, 1885.

To the Editor of The Medical Record.

Sir: I have read Dr. Edson's letter of the 16th ult. addressed to you. It was not my intention to mislead any of your readers, nor to do our worthy Board of Health an injustice. My information was obtained from those who have made coffee both their business and study for years. From them I also learn that, wishing to be certain in their belief that the polishing of coffee was not injurious, Prof. Henry Morton, Stevens Institute, Hoboken, was requested to obtain and analyze samples of the ingredients used, and of the coffee after being polished. I beg leave to quote from his report. . . . "I also took myself from the packages from which they were being used samples of each of the materials employed in the treatment of coffee as there carried on from time to time" (he here gives the names of all the articles used, those mentioned by Dr. Edson). Continuing, he says: . . . "Not one of these substances is of a poisonous character or contains anything poisonous; and, moreover, on account of the minuteness of the quantity used, they would be need to be poisons of the most intense character to do any harm to those consuming the coffee. As a fact, however, none of the substances above mentioned are poisonous in any degree. As to all the substances, it should be remembered that the aggregate amount in the polished coffee is less than one pound to a ton. By operating on samples of usual quantity, say ten to twenty pounds, *traces* of many injurious substances may be found in almost any material. Such traces, it is unnecessary to say, are entirely insignificant, and to detect them by operating on large quantities would be simply misleading as well as useless. In conclusion, I would say that I have found no trace of any injurious substances in any samples of your coffee which I have examined, nor have I found any of the materials used by you to contain any arsenic whatever or anything else which would be injurious to health

under the conditions involved in its use. Any one would seriously injure himself by excessive use of coffee long before he could swallow enough of any of the materials used by you to have any effect at all on him."

It is to be remembered that coffee is polished, if at all, before it is roasted, and should there be any poisonous material on it after polishing, during this process of roasting, the same would be volatilized by heat or carried off with the vapor arising from the coffee, which amounts to about fifteen per cent. of its original weight. I do not believe that there can be any arsenic on roasted polished coffee. I agree with Dr. Edson on the first duty of the Board of Health to stop the free use of insidious poisons in connection with human food, but for that reason they should not overlook the greater for the lesser evil. I cannot agree with him that the roasting of the coffee will destroy all the mould, rot, and offensive materials that may be present in thoroughly decayed coffee. The proof of which may be obtained from drinking a cup of coffee made from roasted "poor skimmings." It is quite certain to nauseate one. I think that Dr. Edson would much prefer to drink a dozen cups made from polished coffee than one made from the "skimmings." I believe that there is a law against the sale of decayed fruits and vegetables under which the sale of decayed coffee can be attacked from a sanitary standpoint.

I am, yours truly, A. WAKEMAN, JR.

NEW YORK CITY, February 25, 1885.

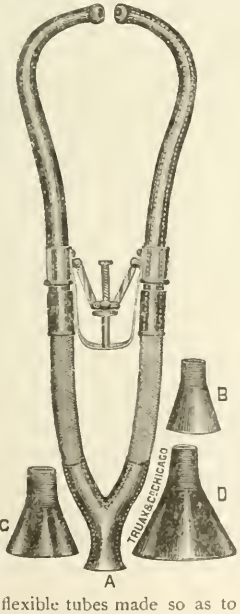
New Instruments.

AN IMPROVED BINAURAL STETHOSCOPE.

BY CHARLES DENNISON, A.M., M.D.,

DENVER, COL.

THE instrument here presented is the result of considerable experimenting and differs from those heretofore used in many particulars which are of great importance in a good instrument, though in outward appearance it is very much like other stethoscopes. The points of dissimilarity are those which I am convinced, by having many different kinds made, are the essentials in a perfect instrument.



1. *As to the quality of sound.* — The material of which an instrument is made determines the character of the sound obtained. A stethoscope made wholly of metal, or with metal tubes only, gives a metallic quality to all the sounds transmitted, whose pitch seems to be elevated and thereby made unnatural. This perversion of natural sounds is not obtained in any such degree by gutta-percha, wood, or celluloid. In this instrument I have chosen hard rubber for the arms instead of the metal heretofore used in most stethoscopes, and have had the flexible tubes made so as to give a smooth inner surface to the coiled wire, which holds them in shape. The manufacturers have succeeded very nicely in imbedding the wire between two tubes of soft rubber and then vulcanizing them together. This arrangement gives nearly as natural effects as does a stethoscope made wholly of hard rubber, which of course would be inflexible and unyielding.

2. *As to the form of the instrument.*—The size of the canal in this instrument is largest at the attachment of the bell and gradually decreases in diameter to the ear ends, and is in imitation of those trumpets or conversation tubes which best serve the purposes of deaf persons, owing to their property of concentrating and conducting the waves of sound. This gradually decreasing channel, which forms one of the principal advantages of this instrument, may be clearly traced by the dotted lines in the accompanying cut.

The larger-sized tubes used in this stethoscope is an especial advantage to those physicians who have slight defects in hearing, and will be preferred I believe by the great majority of the profession. The ear-tips are shaped with particular reference to the direction of the canal in the arms of the stethoscope and have the lower and forward edges bulged to such an extent as to fill in spaces behind the tragi, so that it throws the tube-openings in the direction of the auditory canals. The ear-tips are crowded into the external auditory canal as firmly as can be comfortably done by means of a rather stiff spring, which brings the arms of the instrument together, and which is supplied with a set screw so that it can be regulated to suit the listener.

All the joints, bells, tubes, and arms are constructed on the principle of a slightly conical tube, each portion fitting evenly and tightly into the other, and the fastenings of the flexible portion to the gutta-percha are so perfect that there is no interruption in the transmission of sounds from the chest to the ear.

3. *As to the bell endings.*—These are of my own design, and I have special reasons for the peculiarities of each. There are four of them in number, the smallest (*A*) is the stationary portion and is large enough for use in detecting valvular lesions and for auscultation with infants. The medium-sized bell (*C*) is the one to be most generally used. It has a rim an inch and a half to an inch and five-eighths in diameter, and flaring enough at the edge to give a good impinging surface against the chest-walls, an important feature in every good instrument.

The soft-rubber bell (*B*) fits inside of the medium so that its flexible edges project the fourth of an inch. This is proved to be a very good idea; for, when pressure is made against the uneven surface of the chest-walls, as in emaciated consumptives, every crevice around the edge is filled and the transmission of sound is nearly as complete as with the hard-rubber bell when pressed against an even surface.

The largest bell (*D*), with a rim three inches in diameter, is especially constructed for what I have termed stethoscopic percussion, a process I always make use of when I suspect the existence of bronchiectasis, excavation, or softening. It consists in using forcible percussion over and around suspected portions, chiefly during expiration, while this large bell is held in front of and one to three inches from the patient's open mouth.

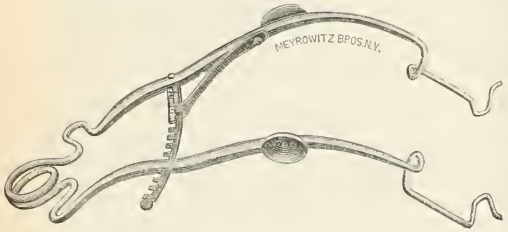
An excavation connected with the bronchial tract is thus very nicely mapped out, the cavernous and cracked sound being brought out with a certainty which cannot be obtained by any other method; because of the fact that the commencement of softening is recognized as a most critical period in every case of phthisis, any improvement in the stethoscope will be appreciated which gives, as this does, earlier and more exact knowledge of the giving way of lung tissue. Hence I make a point of this stethoscopic percussion.

I have had these instruments manufactured by Charles Truax & Co., 81 Randolph Street, Chicago, Ill., who have taken special care to insure all the requirements which I have mentioned, and which I deem essential in a good instrument. Take it all in all, the instrument pleases me better than any stethoscope I have ever seen, and I think physicians who use it will be similarly gratified.

COWGILL'S EYE SPECULUM.

By WARWICK M. COWGILL, PH.B., M.D.,
PADUCAH, KY.

I WISH to call the attention of the profession to a new eye speculum, which has proven, by trial, to be worth bringing into notice. It is a fixation speculum, con-



trolled by a ratchet arm. In adjusting the instrument, the two blades of the speculum are controlled by the thumb and forefinger, while the ratchet arm is controlled by one of the remaining fingers of the same hand. The one virtue I claim for this speculum, above other specula, is that it can be controlled with one hand, which cannot be claimed, I think, for any other fixation speculum.

This instrument, as made by Meyrowitz Brothers, No. 205 Fourth Avenue, New York City, is adjustable for either eye, hugs closely the side of the head, and is entirely out of the way of the operator.

109 EAST TWENTY-EIGHTH STREET.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 22, 1885, to March 28, 1885.

TAYLOR, M. K., Major and Surgeon. Granted leave of absence for one month, to take effect about April 15th. S. O. 46, Department of the Missouri, March 21, 1885.

HAVARD, VALERY, Captain and Assistant Surgeon. Leave of absence extended one month. S. O. 65, A. G. O., March 21, 1885.

RAYMOND, H. I., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Gaston, California, as Post Surgeon. S. O. 30, Department of California, March 20, 1885.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending March 28, 1885 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
March 21, 1885.....	5	10	93	7	156	57	0	0
March 28, 1885	1	6	88	7	144	52	0	0
Deaths.								
March 21, 1885.....	0	3	9	7	18	27	0	0
March 28, 1885.....	0	4	18	6	23	29	0	0

A SPECIFIC FOR TYPHOID FEVER, says Dr. J. W. Hawkins in the Kansas City *Medical Record*, is bromide of potassium in five-grain doses every three hours. It invariably cuts the fever down to seven or ten days. Dr. Hawkins has probably never seen typhoid fever.

THE MINUTENESS OF ANTISEPTIC PRECAUTIONS TAKEN BY GERMAN SURGEONS.—A Berlin correspondent of the *Cincinnati Lancet and Clinic* writes regarding Dr. A. Martin, of Berlin : "During the time of the operation and for half an hour before it is commenced, the spray apparatus is kept going, so that the air in the room, which is a small one, is saturated with the carbolic acid spray. So thoroughly is the air saturated with moisture, that long before the operation is completed the water is running down the walls, and the bystanders' clothing looks and feels like they had taken a bath. The spray is so thick that one can see with difficulty; soon it becomes so irritating to the air-passages that all in the room are more or less inconvenienced from it, and are compelled to cough a great deal. I have seen the spray used by many different men, but I have never seen any surgical operation performed in a room so thoroughly filled by it as here when he operates. Professor Schroeder also uses the spray, but he operates in a larger room and uses a weaker solution of the acid, and has the spray apparatus at a good distance from the patient, perhaps twelve or fourteen feet, and the air is saturated with the spray enough to inconvenience the bystanders. Dr. Martin and his assistants wear linen clothing during the operation, which are washed before they are again worn. All of their usual clothing is removed and the linen only worn during the time of the operation. After the patient is on the table, and everything ready to commence the operation, the visitors are invited into the room; they have been previously requested to remove their coat, vest, and necktie before they enter, and not to leave it until the operation has been completed. Dr. Martin has performed ovariotomy one hundred and five times with four deaths, and sixty laparotomies with mortality of about thirty per cent."

CONTAGIOUSNESS OF SCARLET FEVER.—Dr. M. L. Chambers, of Port Jefferson, L. I., writes : "In view of the recent discussion at the Practitioners' Society of New York City over the contagiousness of scarlet fever in its early stages, the following case may prove of interest. Several years ago I was called to a neighboring village to see a boy, eight years of age, suffering with scarlet fever. There had been no scarlet fever in the village in two years, and never before in the boy's family or in the house in which he then lived. But five days previous the boy's seat-mate at school, who had just returned from a visit at Brooklyn, N. Y., was taken sick with vomiting and sent home, and afterward suffered from what a neighbor, who was considered authority in slight ailments, diagnosed as *scarlet rash*. A sister of this boy died three weeks later with scarlet fever. Three other children in the family of the boy I attended had the disease, and there were altogether about twenty cases in the village during the epidemic. I have no doubt but the disease originated with the boy who had visited Brooklyn, and that my patient caught it from him at school when he was first taken with vomiting, which occurred while they were sitting together in the seat."

A NEW METHOD OF ANÆSTHETIZING.—Under this title, M. Columbel (*Lyon Méd.*, No. 41, 1884) recommends the injection of a Pravaz syringeful (1 to 1.5 grammes) of the following : ℞. Atropiæ sulph., 0.02 ; morph. hydrochlor., 0.20 ; aq. destillat., 20.00. This to be given twenty to twenty-five minutes before the chloroform. The atropia lowers the irritability of the pneumogastric, and prevents the inhibitory effect of the chloroform on the heart. Eight hundred cases have been successfully anæsthetized by this method in Lyons.

COMPRESSED AIR.—The *Weekly Medical Review* says that "it would require a long array of cases, associated with severe demonstrations, to convince us that any simple pneumatic pressure applied to the mouth and nose would favorably compare with an exhilarating buggy ride, facing a gentle and refreshing breeze."

GLYCOSURIA.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,

PROFESSOR OF PATHOLOGY AND CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

OUR ideas of glycosuria may be grouped about the four principal clinical phenomena that characterize the disease, after it has been thoroughly established. These are inordinate thirst; excessive appetite; bodily emaciation; and grape-sugar in the urine. One or other of these symptoms may be wanting in a given case, or at times in the course of an attack; but they are all associated in our minds with every typical example of glycosuria.

Still, chief in importance is one symptom, and it alone will enable the practitioner to perfect his diagnosis; for if grape-sugar be found in the urine, no further evidence is requisite. Sometimes this is the only phenomenon of importance, and if the standard clinical tests in vogue indicate its presence, we know in what direction to institute remedial measures. The term standard tests was employed with due consideration, for they indicate with great readiness and certainty a pathological quantity of sugar. It may be as well at this point to note that Trommer's and Fehling's methods are thoroughly satisfactory in most cases where sugar is present, though on the whole the latter is less apt to be misinterpreted. The characteristic reaction by which, in both, the suboxide of copper is thrown down as an abundant yellowish-red or orange precipitate settles at once the diagnosis, and this characteristic appearance is not seen in normal urine, which contains sugar in minute quantity,[2] even possibly half a grain or more to the fluid ounce.[3] Nor is this point, which was long since demonstrated, a matter that is extraordinary, for physiologists tell us that grape-sugar exists to a certain extent in blood and lymph, and in the chyle during digestion. And so long as it maintains its proper proportion to the other fluids and solids of the body, and is restricted to its regular physiological sphere of activity, we are not concerned about it as a symptom of disease. When, however, it occurs in unusual amount, its presence from that moment is fraught with serious consequences, and if the system becomes at any time overburdened with it we have to contend with an enemy of most dangerous and fatal character.

Grape-sugar seems to be produced very largely in the liver, where it is formed from glycogen in the intervals of digestion.[4] But it is also formed in the intestine through the agency of the pancreatic juice, which is the chief factor in converting starchy substances into sugar;[5] subsequently it is found in the chyle. And it is not merely the ordinary starches that suffer this change, but the whole category of carbo-hydrates, such as cane-sugar, sugar of milk, maltose, dextrine, etc., are susceptible of similar transformation, and it is not improbable that the fats also, and albuminous substances, may, under circumstances to which I shall subsequently advert, be converted into grape-sugar, as Donkin[6] maintained.

It has always been a matter of great interest to discover the reason for this enormous production of sugar in the system, and why it should be robbed so remorselessly of everything in it that can by any means be converted into saccharine material. And for a long time the combined efforts of physiology, pathology, and clinical medicine were unavailing. When, however, Claude Bernard, in 1848, began his series of experiments on this topic, which he afterward followed out with such brilliant results, a new impulse was given to the study, and physiologists repeated and varied his experiments, until now it may be said that we readily understand the manner in which an excess of sugar is often produced, while it also appears probable that in a short time we shall be furnished with the full series of etiological factors.

First and foremost, then, we may regard it as an established fact that the nervous system is commonly at fault, and starting with the famous puncture of the fourth ventricle (Claude Bernard) we have since then found that section of the medulla, the cervical sympathetic and splanchnic nerve,[1] extirpation of the superior cervical, the first thoracic and abdominal ganglia, will produce diabetes, and the explanation is simple, viz.: that the vaso-motor nerves of the liver are paralyzed in each of these instances.

But the action upon the hepatic centre in the lower part of the floor of the fourth ventricle may be reflex. Thus, Schiff cut the sciatic, and irritating its central extremity produced diabetes, and this experiment has been frequently repeated with success, while the same results have been obtained after section and subsequent stimulation of the central extremity of the pneumogastric.[3] And the explanation of the uniformity of these results is based upon the fact that the vaso-motor channels for the liver pass partly through the spinal cord and partly through the sympathetic.

Direct stimulation of the liver may also cause glycosuria. Thus, Harley[3] injected ether and ammonia into the portal vein and sugar appeared in the urine; but Schiff[4] found that puncture of the liver with needles accomplished the same result. The most decisive experiment, however, was that of Pavy,[5] who merely tied the portal, and allowed the liver to be fed solely by the hepatic artery, which is quite capable of sustaining the nutrition of the organ. Sugar appeared in the urine. All of the experiments thus far cited may severally be interpreted, so far as the glycosuria is concerned, from the point of view that in each instance the blood in the liver became unduly oxygenated, and in the absence of any other explanation this one seems to be satisfactory.

But an excess of glucose, or of any substance that is capable of being converted into it, directly or indirectly, through the medium of glycogen, may produce glycosuria, and if we realize that after the injection of starchy or sugary food glucose is found in the small intestine, and subsequently in the chyle, during ordinary digestion in healthy persons, it is quite comprehensible that an excess of these or allied substances may accumulate in the system, and to an extent that they are only partially assimilated. As a matter of fact it is noticeable, in this connection, that the pancreas, whose juices are primarily devoted to the task of converting starchy substances into

glucose, has been found in a large number of cases altered. Rokitansky[1] found it small, hard, and irregular in about fifty per cent. of his post-mortems in diabetics.

This description, thus tersely furnished by one of the most celebrated pathological anatomists of our day would indicate that the organ had been the seat of chronic congestion, and, in the absence of proof to the contrary, we are justified in inferring that owing to some abnormal influence its juices were so diminished in quantity or altered in quality that they were unfitted to perform their ordinary duties; and experiments may yet prove that the same sort of vaso-motor disturbance, if not the identical agency, may affect the pancreas equally with the liver. In fact the province of the former, so far as we understand it, appears to be wholly related to its action either upon the carbo-hydrates, fats, or albuminous bodies,[2] every one of which is capable of being converted into glucose.

But in still another class of instances we may have glycosuria, as when the secretion of a part in full activity is suddenly checked or arrested, in its elaboration of a saccharine material. Thus Lehmann[3] found that sugar always appeared in the urine of women from four to forty-eight hours after the weaning of an infant; the system in such case being suddenly overpowered by an excess of lactose (sugar of milk), and it has been found when there was an obstruction merely to the flow of milk (De Sinety[4]). Of course this position is abundantly sustained by our clinical experience in chronic cases of glycosuria, where, by merely cutting off the starches, sugars, and allied substances, the quantity of sugar in the excretions is reduced to a proportion closely related to the reduction in amount of these carbo-hydrates and their allies.

It is next our plan to inquire into the prominent pathological findings not already noticed, and to observe in how far they support the views that have been advanced. It is to be said, in the first place, that the liver has been frequently found altered (in about fifty per cent. Rokitansky[5] found it brown, hard, and indurated), and at this point it may be well to state that at a recent post-mortem of a diabetic there was marked cirrhosis, though of the variety that has been noticed chiefly in syphilis, where the individual liver-cells are separated by a new deposit of connective tissue; and as a further contribution to this topic the writer recalls to mind a case that has been under his observation where the individual had tertiary syphilis, and possibly, therefore, a cirrhotic liver, and whose restoration to a fair degree of health was ascribed to a six months' anti-syphilitic course.

Though we have thus far implicated the nervous system, liver, and pancreas in the development of glycosuria, it is tolerably clear that the first named is usually the point of departure for the disease, and that the affections of the organs last named play a secondary part. This statement is based upon our clinical knowledge. But it is equally true, though more rarely so, that the liver or pancreas, chiefly the former, may develop glycosuria, through some organic changes in their tissues. Thus Klebs has recorded an instance in which there was a great dilatation of the hepatic and splenic arteries, and gastric branches of the cardiac axis.[6] We need not be detained long with the peculiar appearances described by Dickinson[7] about the cerebral vessels in a diabetic. The characteristics of his case are probably not in any way related to disease, but are those which are found in brains that have been prepared in a peculiar way. This is the view that has been taken by many prominent pathologists. The "vacuolization," or "Gruyère cheese" formation, was probably due to an unnatural dilatation of the lymphatic channels, caused by the shrinkage of the cerebral tissues, from the use of alcohol as a hardening reagent. Richardson's[8] findings are noteworthy, for he narrates that he found an ossific growth pressing on the pons.

Von Frerichs[1] found a fibro-myoma of the pneumogastric the size of a pea pressing on the floor of the fourth ventricle.

Harley,[2] in one case, found a clot pressing on the fourth ventricle, and extravasations of blood have been noticed in the spinal canal, the clot causing vaso-motor paralysis, possibly by the pressure brought to bear upon the vaso-motor nerves. Numerous findings of similar bearing have been published.

We next pass to the kidneys, which naturally hold a subordinate place in our study of diabetic pathology, for though they serve as the media by which the saccharine blood of the kidney is converted into urine they are not affected unfavorably until the disease has become chronic. At least this is the conclusion to be derived from clinical experience, for it is only in advanced cases that we detect the swollen and granular condition of the parenchyma. No doubt this renal complication occurs in a large proportion of the cases. (Rokitansky says sixty-seven per cent.) Of course, if such a volume of water passes through the organs, it is but natural for them to increase in size, and the passage of sugar would be apt, by its irritating qualities, to cause an infiltration of the epithelial elements, both of which characteristics belong to the advanced stages of the disease.

The lungs next claim our attention. Dickinson[3] found them ulcerated and inflamed in twenty-five out of twenty-seven cases; Griesinger[4] found tubercles in thirty-nine per cent. The precise nature of the pulmonary difficulty is still *sub judice*, Pavy and Dickinson denying the tubercular nature of the affection.

In this connection it is interesting to note some recent studies by Leyden.[5] He found at the autopsies of diabetics that often miliary tubercles were absent, or that there was no general eruption, or, finally, that a sort of obliterating arteritis was present, and that as the result of it certain lung territories had become necrotic, exhibiting the so-called coagulation-necrosis of Cohnheim. This tendency to disease in the smaller arteries was due, whether in the lungs or elsewhere, to the diminished quantity and thickening of the blood, cardiac weakness, and loss of muscular force, especially in the respiratory muscles.

Whatever be the proper view of this question, it is evident that the lungs are not primarily affected, and this conclusion is based upon clinical experience, which shows that in the prediabetic period of life there are proportionately fewer manifestations of pulmonary phthisis than in ordinary individuals taken from a general average. We may take the occurrence of phthisis in the community at large at the figures of 1 to 7 (an average estimate). But in my cases it was in the prediabetic stage as 1 to about 13. This result, then, so far as it shows anything, proves that phthisis is comparatively seldom the precursor of diabetes. Of all complications of glycosuria, the most frequent and the most dangerous is the morbid alteration of the kidneys, evidenced by the occurrence of albumen and casts in the urine, and other symptoms which are classed as uræmic.

The foregoing considerations have prepared us for the study of the etiology of diabetes, and have indicated the sources of the disease. As in many others, there is in glycosuria often a hereditary influence, possibly a congenital weakness of the nervous system, or an undue susceptibility to external impressions. This is shown by the fact that its origin is frequently traced to a mental or physical strain, especially in families where there is insanity, epilepsy, or functional nervous disturbance of any sort. With them a violent mental shock, or blow, in which the nervous system receives the most damage, es-

tablishes the disease. Often several of these etiological factors combine, as in a medical student formerly under my tuition, and under the medical care of a colleague. He was a young man, quite obese, and therefore a good subject for diabetes. While preparing for his medical examination, he became suddenly straitened in his finances, and took to drinking lager beer to excess. Glycosuria set in, very actively, no less than four gallons having been passed in one day. After diabetic treatment had been instituted, with bromides and opiates, the unfavorable symptoms yielded and disappeared altogether within eight weeks. Whether exposure to cold or dampness or malarial poisoning should be considered as causes of the disease, are topics that may still be questioned. There is no doubt that a male subject who has passed the middle period of life is in most danger.

We shall best come to an understanding of the clinical phenomena of the disease, if we realize, as the evidence before us clearly demonstrates, that there are three tolerably distinct forms of glycosuria. They may be designated as: (1) *temporary*, of which an example has already been given in the case of the medical student who drank four quarts of lager beer, and in whom, under sedative treatment and a restricted regimen, recovery took place in a few weeks; (2) the *mild* form, in which the disease will continue for years with few symptoms that distress, and all of which may be regulated or mitigated by appropriate treatment, so that the diabetic will improve in strength of mind and body, and concern himself but little about his sugary urine. The classical features of this disease may be so modified that he cannot be said to have "inordinate thirst," "excessive appetite," or "bodily wasting;" and though he have sugar in the urine, he may pass little or no more than in health. Such cases are comparatively uncommon, but occur occasionally among old and obese men, though sometimes in the middle period of life. They serve to indicate, however, that the term diabetes, indicating, as it is intended to, an increased flow (*dia*, through, and *baino*, I flow), is a misnomer. And since the only one constant symptom is sugar in the urine, we may more properly use the word glycosuria, which covers the ground precisely and satisfactorily.

In fact, the word diabetes is practically equivalent in significance, though not so precise, as polyuria, which indicates merely a clinical condition, common to the so-called diabetes insipidus, all forms of the sclerotic kidney, certain neurotic disturbances, and glycosuria. This form we may call (3) the *severe*, it is the classical variety with which we are best acquainted.

With this broad classification of the disease in types we may undertake the consideration of some details that bear upon its symptoms. Though the disease is most common in males and about the fiftieth year of time, it has occurred at almost every age. A child of twenty months has had it, and in the young it is commonly severe and rapidly fatal.

In the majority of instances, it progresses steadily to a fatal issue. At first there is a premonitory lassitude, with certain dyspeptic symptoms, such as flatulence, possibly vomiting; there is also usually neuralgia, and often dizziness. Though the patient feels that his strength is failing, he does not consult his physician until the thirst at night urges him to get up to satisfy it; then he appreciates that his urine is becoming excessive in amount, but, though his appetite is good, food does not seem to give strength. The urine is usually of a light yellow color, thick in consistency, sweet to the smell, and has a high specific gravity. The skin is now apt to become dry, the countenance pale, and the lips seem to be covered with sordes, but it is merely a collection of sugar. All of these symptoms may improve under treatment, but they usually do not, the patient gradually but surely failing—his thirst becoming more inordinate, his appetite more acute, while he is constantly craving for starchy food.

As he emaciates, boils are apt to break out on his body. Sexual power fails, and, in about one-half the cases, cough sets in, and pneumonia or phthisis is established. Death may ensue from either of these complications, or the urinary symptoms may abate, the sugar diminishing, and with it the thirst, and improvement appears to be at hand, when it is suddenly apparent that a new complication affects the prognosis: for, although the amount of sugar may be reduced to a minimum, or even disappear entirely, and the specific gravity fall to the normal, and with it the volume of water, albumen and casts will be detected in the urine, and the kidney is now the source of greatest danger, for coma may at any time supervene and be the last scene in the drama. This last complication is not generally recognized by those who have written on urinary diseases, but it is a condition which is most common. In rarer cases sudden coma may ensue, and from the peculiar reaction that is given to the urine by the perchloride of iron, acetonæmia is believed to have been developed, causing the fatal issue. It has been my experience that in a goodly number of cases, the urine being in great measure suppressed, it is not examined, or else we should find that the coma is uræmic. In doubtful cases, a catheter should be used to draw the water for examination. Death sometimes occurs from cardiac failure, showing that the heart must always be sustained where it is known that the danger lies in this direction. When uræmia is impending, it will sometimes be observed from the sudden swelling of the lids, face, or extremities; the headache will become more marked, the mind clouded, and gastric symptoms more pronounced. But, owing to the watery condition of the blood, œdema of the extremities may occur independently of nephritic trouble.

An attack of diabetic coma may be thus described: It is insidious; occurs with prostration, headache, restlessness, and anxiety, pain in the epigastrium, nausea and vomiting; suppression of urine: the pulse, at first quick and feeble, is afterward slow and intermittent. The breathing is short, labored, and superficial. The mind is disturbed, and memory often for the time affected. There may be delirium. It has been thought that an attack can be induced by a diet rich in albumen, but poor in starch. This is probably true. Such attacks must be differentiated by apoplexy and alcoholism. Whatever may be the immediate cause, they will supervene sooner or later in the majority of cases.

In the mild form of the disease the unfavorable symptoms are often brought immediately under control by a proper dietetic treatment, with or without medicinal reagents. In many of them there is but little, if any, increase in the quantity of water voided, the disease is characterized by intermissions of such length that the patient imagines himself cured; the disease is not only arrested, but the symptoms have very much improved. I have in mind such a case. The patient was attacked seven years ago. He suffered much from thirst, inordinate hunger, and nervousness. He had been syphilitic. No remedies appeared to do him much permanent good, until he was put upon a full six months' course by his physician, and now he appears to be in much improved general condition, has regained his strength and weight to a marked degree, has a florid complexion, and is only disturbed by his thirst, which he allays by drinking red wine in moderate amount at meal-time.

The incidental form is observed after whooping-cough, asthma, poisoning by chloroform, carbonic oxide. Its character is so evanescent that it seems as if it can hardly be called a disease.

From a review at this point of the records of physiological study, experimental pharmacology, morbid anatomy, and clinical medicine, it may be seen that we are prepared to understand most of the conditions under which glycosuria exists, and it is not improbable, as has been already intimated, that the solution of the remaining problems will not be difficult. It would appear, then,

that there exists in certain families a tendency to the disease, which has for its very near relations certain nervous disorders, such as insanity and epilepsy; among skin disorders, eczema. In this class of persons more than in others, a severe mental strain or a physical shock, in which the nervous system is profoundly disturbed, glycosuria is apt to occur; though with a suspension of predisposing and existing causes, there is apt to be a suspension or suppression of the glycosuric symptoms. But the method by which the influence is brought to bear upon the system is through the vaso-motor system, the medium being either the sympathetic directly or indirectly. Under such pathological action a disturbance of the hepatic circulation takes place, by which probably the blood of the liver is unduly oxygenated, the experiments of Pavy being apparently conclusive on this point. Again, any injury to the liver substance, such as laceration, may cause the same condition, and therefore we infer that a special irritation of the hepatic cells is also competent to produce glycosuria. But the amount of sugary material or carbo-hydrates, ingested fats, or albuminous substances, all of which are capable of being converted into sugar, may be so great that neither the liver nor pancreas can assimilate them, and they will therefore appear in the excretions; or finally, it may be possible that the pancreatic juices—whose provinces embrace the conversion of starch into sugar, emulsification of fat and solution of albuminous matters—are so altered in quality or quantity that they do not perform their proper office. In support of this view the pancreas was found diseased by Rokitansky in about one-half the post-mortems of diabetic patients, as already stated, and other changes noted by Klebs, Frerichs, and Recklinghausen,[1] would appear to offer corroborative evidence.

In glycosuria the amount of water passed during twenty-four hours will vary, in uncomplicated cases, from forty ounces or thereabouts to several gallons. In the mild form the quantity may not be increased above the normal. In a severe form Bence-Jones has known seven gallons to be passed. A fair average would be about four quarts. But it is known pretty positively that the amount passed does not exceed the amount of fluids taken into the body by way of drink. The specific gravity varies from 1.015 to 1.060 and more, with an average of perhaps 1.030 to 1.035. The quantity of glucose will vary from seven to twenty-five ounces in weight, and has reached two pounds. An average of four to five ounces of sugar represents the ordinary amount. Urea is always in excess; sometimes it reaches five times the normal quantity.

Of the twenty or more tests for sugar it is needless for us to detail them all; but an enumeration of them may be interesting: (1) There is the polarization test; (2) then that with caustic potash; (3) with quicklime; (4) with common salt; (5) with potassic or sodic hydrate; (6) with caustic potash and sulphate of copper; (7) with indigo-carmine; (8) by fermentation; (9) by the ammoniated solution of nitrate of silver; (10) by the carbonate of sodium and subnitrate of bismuth; (11) by the hydrate of potassium and molybdate of ammonia; (12) Fehling's; (13) Fehling's, modified by Pavy; (14) Trommer's; (15) Moore's; (16) Bence-Jones'; (17) Brücke's; (18) Johnson's picric acid[2] and potash; (19) Roberts' differential density, for quantitative analysis.

For practical purposes Trommer's and Fehling's answer satisfactorily for qualitative analysis, and Roberts', the volumetric, or Johnson's for the quantitative. Moore's is now abandoned, because it will not indicate a proportion of sugar less than two grains to the ounce.

The objection to Fehling's volumetric test is that it is not always easy to determine at what point the blue color disappears, for the cuprous oxide still remains after the cupric oxide has disappeared. This difficulty has been met by Pavy (Johnson), who adds ammonia to the mixture.

[1] See Coats: Manual of Pathology, p. 78.
[2] See Neubauer and Dogel, p. 101.

In practice this method has its disadvantages, because the ammonia given off is extremely disagreeable, and air must be excluded during the test.

For those who can detect slight changes of color or tints, George Johnson has devised a picric acid and potash test that offers some special advantages for bedside use, as the apparatus can be carried in the pocket and both the qualitative and quantitative examination made in the consulting-room. This apparatus, however, has (according to his admission) the following disadvantages, which are sufficient to prevent its being generally accepted. In the first place, the standard solution changes color by exposure to the light, and must, therefore, be kept under cover, and secondly, we may assume that a large number of persons cannot appreciate the shades of color by which the quantity is estimated. We are therefore obliged, for the present at least, to fall back upon Roberts' differential density test, which in practice will be found to be second only in point of precision to the cumbrous method of evaporating to dryness an ounce of urine, washing and weighing the residue.

From the reports that we now have access to it would at first appear that the disease is increasing in frequency, but it should be remembered that we are more prone to detect it now than formerly. According to English statistics taken during the decade from 1851–60, one death from glycosuria occurred annually in an average population of 40,000; but in some instances the proportionate mortality is much less. In some statistics it is given as 1 to 86,000; in others 1 to 68,000. Of cases treated at the New York Post-graduate School and Hospital there were only 3 in the first 10,000. Romberg found 3 to 10,000 at the Vienna Polyclinic. The following statistics were derived from a study of 40 cases which I have collected in my own experience and in that of my friends. It occurs more frequently in males than in females; of my cases 27 were males, 13 females. The age varied from nine to eighty years, but the disease began in the larger number after middle life had been passed. In many instances the early symptoms were referable to the nervous system, but in most the premonitory symptoms were ill-defined.

The exciting cause in seven was set down as abuse of alcoholics; in four, mental anxiety; in four, concussion of the spine; in one, sexual abuse; in one, the opium habit; in one, syphilis. The specific gravity varied from 1.015 to 1.044; the amount passed daily from two quarts to four gallons; the amount of sugar per ounce from five grains to forty grains. But few post-mortem examinations were made (three), and the findings given were: in one, cirrhosis of the liver; in one, peri-hepatitis; of pulmonary lesions, in two, congestion of the lungs; in one, gangrene. The treatment in two only was successful (five per cent.), and the method employed in one was codeine in small doses, with a restricted diet; in the other, preparations of opium and the bromide of potassium, with a restricted diet. The disease was also arrested in two cases (five per cent.), in one by iodide of potassium and Fowler's solution; in the other by bromide of sodium in large doses (thirty grains), three times a day, and ergotine. These last two cases were regarded at times as cured. Improvement followed in eight cases (twenty per cent.), under 1, Fowler's solution; 1, codeine, skim milk, and restricted diet; 1, jaborandi and pancreatized milk; 1, opium, cod-liver oil, and iron; 1, cod-liver oil, sulphide of calcium, and dietetic treatment; 1, iodide of potassium; 1, dietetic treatment alone; 1, restrictions as to sugar only.

The complications were, so far as noted: pneumonia, 2; phthisis, 7; Bright's disease, 7; albuminuria, 1; coma, 3; acetonæmia, 1; sloughing ulcers of feet, 1; eczema, 2; and hemiplegia, 1. It will be observed that though there is a lack of definiteness as to the precise nature of some of the complications, the chief dangers are from the lungs or kidneys, and it is not impossible that the instances of coma may largely have been due to uræmia, which in

my view of the case is the most frequent cause of death. Whether in the cases where phthisis was recorded as a complication, tuberculosis was intended, is a matter that cannot be decided at present.

The duration of the disease is usually (on a general average) from one to three years, though death has occurred in eight days; and one only of Griesinger's 100 cases lived seven to eight years. But there is a case on record in which the patient lived eighteen years. It has been said by Vogel, that gouty persons and those who live on rich food have a comparatively favorable prognosis. He treated such a case in an old person for ten years or more, and the general health was but slightly disturbed. The younger the person, *cæteris paribus*, the more unfavorable the prognosis. We have already observed that complications affect the prognosis. Thus, according to some statistics one-half the cases have pulmonary tubercle. There is also a tendency to pneumonia which may cause death independently of the diabetes. Then gangrenous inflammations have their influence in determining a fatal issue. In a case under my observation, death was much accelerated by this condition, though phthisis and parenchymatous nephritis also had their part. It is possible, indeed, as it has been stated, that carbuncles may cause death.

According to the reports of the London Hospital for eight years, coma caused death in 19 out of 37 cases, and pulmonary phthisis in 9. According to Guy's Hospital Reports, 33 out of 53 diabetics died comatose, but death may occur from sudden heart failure. According to my own statistics of 40 cases, the causes assigned were as follows: Pneumonia and suppression, 1; pneumonia and cardiac failure, 1; pulmonary hemorrhage, 1; phthisis and coma, 1; phthisis and nephritis, 1; hemiplegia and nephritis, 1; nephritis, 1; coma, 2; acetonæmia, nephritis, 1. Thus we see that kidney and lung diseases are the factors most prominently concerned in the causation of death.

One of the first principles to be laid down in the treatment of glycosuria is that a strict dietetic regimen should be enjoined, so that all sugary and starchy food, together with all substances capable of conversion into them be excluded from the diet. But while this plan is imperative, it is often hardly less desirable that the change be not made too suddenly or completely. We should be satisfied with throwing over first one and then another of the carbo-hydrates, until none remain. Some persons can, without much suffering, accommodate themselves to their altered mode of life; others cannot, so well, and will seek and find opportunities to break in upon the restrictions. But the physician will more often be called upon to treat the concurrent symptoms, and perhaps first of all the neuralgic and muscular pains. The bromides often are sufficient, but sometimes opium or its alkaloids have to be resorted to. Perhaps as popular a remedy as any for these phenomena is codeine, first recommended by Pavy, for it accomplishes the result and without increasing the constipation that is often so aggravating a feature of the disease.

Ergot and ergotine have been found successful, and indeed they are indicated as remedies to combat vasomotor paralysis. An empirical remedy which is thought well of by several of our best clinicists is Clemens' solution of the arsenite of bromine, of which the dose is three drops three times a day. The sulphide of calcium in from one to three-grain doses, three times a day, has been used with good effect by two practitioners of my acquaintance.

Gluten and bran breads have not met with general favor for any great length of time. Patients usually object to them as being unpalatable. A point of practical importance in the management of any such case is that the patient should be made to understand that the more rigidly he adheres to the restricted diet, the sooner will the unpleasant symptoms disappear, and that he may hope, after from six to eighteen months of treatment, to be able to return to a mixed diet. When this favorable point is reached the carbo-hydrates should be gradually one by one restored to the food, but only if there has been a total absence of sugar for several months. Of course all diabetics should be made to understand that their position is never free from danger.

Most often complications set in, and these have to be guarded against. The danger may come from the lungs, from the kidneys, the heart, or even from the skin. Symptoms indicating such implication of organs should be duly noted, and it is therefore desirable for the diabetic to report frequently to his physician, and especially that his water be regularly examined. Once a week, when under treatment, is not too often, and then nephritis will be recognized in time to guard against it. Necessarily, then, the treatment of diabetics must be always in the direction of the greatest danger. Pulmonary complaints must be met with cod-liver oil and iron; nephritis with iron, digitalis, and diuretics in general; when the heart must be sustained, by alcoholics or diffusible stimulants, and the nervous disturbances regulated by sedatives. Coma is the most insidious and dangerous symptom; though cardiac failure is hardly less alarming. As has been indicated, the coma is usually uræmic, and we, therefore, should be prepared for the most active treatment to relieve suppression. Sometimes when other remedies fail and coma is deepening, the muriate of pilocarpin by hypodermic injections in three-fourths grain doses, will have a most happy effect. In advanced cases it may be desirable at times to return to a mixed diet, rather than run the danger of nephritis, which appears sometimes to be set up by the use of nitrogenous food. Whether the trouble be renal or cardiac, treatment, fortunately, if well directed, will carry the patient successfully over many alarming attacks.

HOW MUCH SHALL THE DOCTOR BE PAID?

By HENRY A. RILEY, ESQ.,

NEW YORK.

In considering the question of the amount of compensation due the physician or surgeon for his professional services, there are two or three preliminary points which require an answer favorable to the practitioner. There must be no doubt as to the fact of the services being faithfully and skilfully rendered, and the charge of malpractice must not be raised against him. If there is a question as to the skillfulness of the treatment the compensation may be seriously cut down, or if an improper and harmful mode of treatment has been adopted, the right to any compensation at all may be denied, and the patient allowed to recover damages instead.

Under the usual circumstances, however, of skilful treatment the interesting question presents itself of the amount which the physician can properly ask from the patient.

It may be said at the outset that there is no legal rule requiring all practitioners to accept the same fees for the same services. The professional eminence and knowledge of some members of the guild makes it proper for them to ask and to receive higher rates of compensation than those given to young and inexperienced men. This is a sound principle in law and in common-sense, and will be respected by courts and juries. The importance and delicacy of an operation or mode of treatment are, of course, to be considered in estimating the amount of a charge. The wealth of a patient is also an element to which some weight can be given, and within proper limits larger charges, based upon this consideration, will, no doubt, be allowed by the courts.

It occasionally happens that a physician will make an agreement with his patient to make no charge unless a cure is effected. Such an agreement is a foolish one on the part of the physician, as it obliges him to take the risk of contingencies which may be absolutely beyond

his control. The physician has no infallible knowledge which will enable him to predict with positive certainty the outcome even of a slight ailment, and much less is this true of the result of more serious ones. The promise, then, is objectionable in itself as presuming upon the prerogatives of a Power higher than that of the physician. In addition to this the risks of such a promise are needless.

If a promise of this kind is made, however, the physician will be held to it absolutely. Nothing will excuse the failure to effect a cure. In the case of Smith *vs.* Hyde, 19 Vermont, 54, the physician made this agreement with his patient, and afterward during the course of the treatment, feeling uncertain about his payment, asked the patient's son for some security. A written guarantee was then given by the son, and when payment was refused suit was brought upon this guarantee. It was shown on the trial that a cure had not been effected, and although the guarantee made no reference to this agreement and did not seem to have been made in connection with it, the Court held that there could be no recovery. The guarantee must be construed in subordination to the "no cure, no pay" agreement. When there is no express promise to pay a fixed amount for a physician's services, and this is usually the case, the law implies a promise to pay what is reasonable. The gauge of what is reasonable is largely in the physician's control, but when a dispute arises a jury becomes the final arbiter, and the practitioner is obliged to accept its estimate of the value of his services. As juries are uncertain bodies, at one time giving large verdicts, and at another cutting down the recovery to meagre limits, it can hardly be said that the physician has any way of accurately forecasting the result of a suit.

Juries in the city will be likely to give a higher rate of compensation than similar bodies in the country, and the professional position of two physicians may be so diverse, that very different amounts may be given in the two instances for exactly the same services.

There being, then, no invariable rule to govern these cases, the only way to secure information as to the compensation which juries deem to be reasonable will be to consider some of the cases as reported in the law-books.

It may be said that the tendency of the average juryman is to give the physician less than he asks. Perhaps this is done for personal reasons and because the juryman knows that sooner or later he will be obliged himself to receive a physician's bill; and he wishes to impress the profession by his verdict, for his own advantage, with the idea that small bills are to be preferred to large ones.

In Baxter *vs.* Gray, 4 Scott, N. R., 374, an English case, a surgeon rendered services to a certain Mary Bostwick from 1829 to 1840, but expecting that a legacy would be left him, did not present a bill. At this time and until 1858 in England there could be no recovery for medical services unless there was an express promise to pay. Upon the death of the patient, without mentioning the surgeon in her will, a bill was presented to the executors for £500. Payment being refused, suit was brought and a verdict secured for £250, but the record does not show the extent or value of the services rendered. It can only be inferred from the length of time (eleven years) that the claim might fairly be a large one.

In another English case, Stackman *vs.* Vivian, 34 Beav., 290, the physician treated a lady for several years, but received no compensation, except on one occasion when he was called to attend a servant in her family. On the day before her death, the lady wrote to her executors asking them to remunerate the doctor in a handsome manner, and in addition she gave him in her will £3,000 and a reversionary interest in £6,000 more. The physician was not satisfied with this, but brought suit for his fees. There does not seem to have been an express promise to pay, and it was proven on the trial that the physician had treated other persons without having sent in any bills. His claim was, therefore, disallowed by the court. It would seem in this case as if the physician had been well paid, and that the suit ought to have been decided against him.

In an interesting case in Louisiana, decided in 1856 (Succession of Victor Duclos, 11 Louis. An., 406), there were two physicians attending a patient; one of them, Dr. Aufoux, presented a bill for eighty visits, day and night, amounting to $175; and for thirty consultations, amounting to $300, the whole bill being $475. The other physician, Dr. Natili, put in a bill for $320, without specifying the character of the services. On the trial the jury gave $195 to each physician. The verdict was appealed from, and the court held that even this amount was too large. It was decided upon the evidence that only two visits in each case were entitled to rank as consultations, and that there were fifty-four visits in all paid by Dr. Aufoux, and fifty-two by Dr. Natili. The court further held that when there was contradictory testimony as to the proper charge, it was right to take the lowest estimate given. On this theory the court took the rate given by one physician, who testified that a reasonable charge would be $10 for the first consultation, and $5 for subsequent ones, while for ordinary visits $2 might be charged for the first and $1 for subsequent ones. On this basis Dr. Aufoux was held to be entitled to $15 for consultations and $53 for other visits, or $68 in all, and Dr. Natili to $66. This was certainly a heroic reduction, and while it may have been warranted in this individual case, it can hardly be said that the rule for the court to take the lowest rate of charges testified to as reasonable by different experts, is necessarily binding on the courts of other States.

A physician is not absolutely bound as to the value of his services by the bills he may have presented. If payment is not made promptly he can bring suit for what he deems reasonable, and the jury will give a verdict on the *quantum meruit*.

In Miller *vs.* Beal, 26 Ind., 234, where the question was in regard to the value of an attorney's services, the principle being the same as in the case of a physician, it was held that the "demand upon the appellant for payment of a sum named could only be regarded as a proposition to receive that amount in discharge of the debt, and as furnishing evidence to the jury of the value placed by the appellee upon his own services. Payment of the sum demanded would have been an acceptance of the proposition, and, no amount having been fixed by previous contract, would have been conclusive upon the parties. In the present case there was evidence from which the jury might find that the proposition was not accepted, and that the services were of greater value than the sum demanded."

It may be said, however, as a practical rule, that a physician had better stick to a bill once presented, no matter how small it may have been, and notwithstanding the fact that it was intentionally made lower than usual to induce prompt payment. A jury will not be inclined to view with favor any increase in a bill from what it was originally. This, at least, is the experience of the writer in testing the temper of juries in similar circumstances.

The physician, as a usual rule, is not an expert bookkeeper, and his books, when brought before a jury, not infrequently cause derision. It is necessary, however, in most cases to present the original entries for examination whenever there is a dispute in regard to the number, character, or value of the visits made. It is not proper to make a general and indefinite charge of "medical services." Dates will be required as well as the number of visits.

In the case of Hughes *vs.* Hampton, Const. Rep., 745, a South Carolina case, the physician made a lump charge of $13 for medicine and attendance on one of the general's daughters in curing the whooping-cough, and the natural objection being made that the charge was too vague the plaintiff was not allowed to recover.

In Simmons *vs.* Means, 8 Sm. and Marsh, 397, a Mis-

sissippi case, tried in 1847, the plaintiff sued for $150 for medical services and recovered $130, which verdict was reversed on the ground of insufficient evidence. It was held that a physician should show that he kept correct books, and that the account sued for was correctly copied from these books, upon which evidence he will be entitled to recover the amount of his account, but in all other particulars the physician must be held, like other persons, to the customary rules of evidence.

In Lance *vs.* McKenzie, 2 Bailey, 449, the Court said: "The usages of the medical profession have given to their professional services for the most part a fixed value. And the value may be ascertained with a tolerable degree of certainty from description. This the physician may furnish, and he is bound to do it, as the means of informing the judgment of a court and jury as to the value. Without it he is the sole judge of the measure of his reward; and, however safe that privilege might be in the hands of liberal and honorable men, it would be unsafe to confide so much to any class of men. The rules of the Medical Society of South Carolina, by which regular physicians are usually governed, prescribe, as I am informed, specific rates as far as specification is practicable; and, as far as my own intercourse with the profession extends, they are observed with great particularity. They owe it to themselves as the means of avoiding suspicion of extortion to be thus particular, and, as it is alike necessary to protect the community from imposition, it ought to be rigidly exacted. The rule that medical charges must be specific is distinctly laid down in Hughes *vs.* Hampton (cited above), and has been invariably acted upon ever since. One of the witnesses on the trial states that his own habit was to charge for medicine generally without specifying kind or quality. Between him and his patients the court disclaims the right to interfere; but if he come here and is put upon his proof, he will be obliged to make out his case according to the settled rules of evidence."

The existence of epidemics does not allow excessive charges to be made. This point and the further one of particularity in charges came up in Collins *vs.* Graves, 13 Louis. An., 95, in 1858, where the following bill was presented:

J. W. Graves

To R. T. Collins, Dr.,

1855. To waiting on himself, wife, daughter, son, and negro woman during the yellow fever, at $100 each..... $500

The jury returned a verdict for $150, with interest. The testimony as to the value of services rendered during yellow fever epidemics was contradictory, some witnesses testifying that double the ordinary rates were customary, others that it was usual to make a charge of $100 for heads of families and $50 for each other member.

No evidence was presented as to the number of visits and the court held that under the Louisiana decisions the lowest rate was the proper one; but as the record did not show the number of visits, a new trial must be granted.

These citations do not cover by any means the various questions arising in cases involving the amount of compensation due physicians, but they show some of the principles involved.

For the Country Doctor.—An Englishman has devised an arrangement for driving a horse with one's feet. The feet rest on a firm board, and the horse is guided by raising or lowering the toes, thus bearing on one or other rein by means of straps in connection with them, which pass over the pulley mounted on the front board of the vehicle. The driver's hands are quite free, and may be inserted in the pockets of his great-coat, or grasp firmly a hot potato.

REMOVAL OF THE UTERINE APPENDAGES—RECOVERY.

By MARY A. DIXON JONES, M.D.,

Brooklyn, N. Y.

Miss A. Y——, twenty years of age, had been an invalid seven years, suffered with constant pain in the pelvis, increased at the menstrual molimen, and had various reflex nerve-symptoms. Her whole nervous system seemed to be greatly disturbed and in an abnormal condition. She was the younger of two children, both parents living; mother was extremely nervous and especially depressed before the birth of this child. The patient when young was not strong. Menstruation commenced at the age of thirteen, but a year previous to its occurrence she suffered with constant pain in the right side of the pelvis, so great that a physician was called in—a homœopathist—who said "it was because her courses were coming on," gave her some drops, and made no other effort to relieve her, or find out the trouble or the cause of her suffering. We regard menstruation as a physiological function, and not necessarily attended with pain. If the genital organs are healthy, and the system in a proper condition, there will be no special trouble or distress; and when there is much trouble or suffering, there is always something wrong locally or constitutionally.

The pain in the side continued to grow worse, the distress at the menstrual period lasted longer and was more severe, and she was less and less able to sit up each time; said, "I went myself to a doctor in New York to see what the matter was." This second homœopathic physician diagnosed her case as threatened hernia, to prevent which, he had from time to time her whole abdomen bandaged with strips of adhesive plaster. The next physician treated her for uterine disease. The second physician was again consulted, who said there was not anything the matter but a little displacement of the uterus, that could be easily cured, and he introduced a pessary which gave her most intolerable distress.[1] Another physician was consulted, who said she had curvature of the spine. Next physician treated her for "spinal irritation," cauterized each side of the spine, etc. After this she was treated by various physicians for "various nerve-troubles" and "head-symptoms." The next medical man pronounced "the whole difficulty to be a tape-worm," and proceeded by various medicaments to expel it, but it never came. After this she was sent to a homœopathic hospital, where she remained seven months, and her case was published as a cure in one of their journals.

After her return from the hospital she was still sick and suffering, and was attended by many physicians. Some recognized the backward displacement of the uterus; various pessaries were introduced; in all eighteen different kinds were tried during her sickness; each one, she said, was "perfect torture." The last one suggested was McIntyre's interuterine stem pessary. Fortunately she was spared this experiment.

At this time twenty-one doctors had attended her, but, notwithstanding their treatment and their various hypotheses, she was still growing worse, more and more of an invalid, suffering more and more distress, till she was confined to her bed most of the time, and "did not leave it for a period of eighteen months." Now was recommended coccygectomy. I saw her first June 18, 1884. She was in a weak, prostrated condition, suffering with great nervous excitability, complaining of pain in her head, down her spine, around her waist, and in the pelvis. She was pale, pulse feeble, flesh flabby; temperature, 100°, pulse, 95. I could find no evidence of organic trouble of any organ till I came to the examination of the pelvis; here I found the uterus completely retroverted, fundus near the anal orifice, os uteri one-half inch from the ostia vaginæ; left ovary enlarged to nearly the size of a small kidney, dislocated downward, and ex-

[1] Probably at this early period there was some oophoritis.

tremely sensitive. The right ovary was in a similar condition, and surrounded by peritoneal inflammation. The Fallopian tubes were indistinctly felt. At this first examination I informed the parents there was chronic inflammation of the ovaries, probably cystic degeneration, and some salpingitis; and that I believed the patient could be cured only after the removal of the uterine appendages. Still I recommended that she should have medical treatment, with the hope of relieving her distress, improving the condition of the nervous system, and, if possible, curing her without resorting to an operation. The father cordially accepted the idea of the diagnosis, expressed himself as convinced that such were her conditions, though, said he, "it is the first time it has ever been mentioned to me."

The patient spoke of the great soreness in the rectum, from which she had suffered for years; said that "every operation on her bowels hurt the back of the womb"—"always gave her distress, except when the bowels were very loose"—"it was extreme soreness, pain frequently lasting for hours, and pierced right through to the front." She also referred to her great suffering during menstruation, how at all times "the pelvis felt heavy and swollen, a constant bearing down, a dreadful feeling which extended up to the chest and down the legs. And in the legs there was a numbness, pain, and a prickly sensation."[1] At another time she expressed her feelings in these words: "Pain and weakness extreme in every part of the body, and a fearful nervousness."

I requested Professor B. F. Dawson, of the New York Woman's Hospital, to see the patient. He examined her very carefully as to any spinal trouble, found none, recognized the displacement and the disease of the ovaries, and thought much of her suffering and disturbed nerve conditions were due to reflex irritation, resulting from the diseased condition of the ovaries. He also cordially approved of making every effort to relieve and cure her if possible without subjecting her to an operation.

She was put under a course of treatment, medical and hygienic. She had massage twice a day, was kept quiet, bathed regularly, slept well, and had good nourishment. At the same time I made efforts to reduce the inflammation of the pelvic organs, and as soon as the tenderness would allow, endeavored to replace the uterus, and retain the ovaries in position. In some respects she seemed to be better, yet I could not perceive that the condition of the ovaries and tubes was in any respect improved. She was still suffering every day with pain and distress. I even believed their condition was growing constantly worse; and apparently they were incapable of any improvement. There was nothing left but to remove the diseased structures. The father was anxious for the operation to be performed as soon as possible, even desired it to be done during the month of August. He said "he knew it should be done, and he would take the risks."

At this time I requested Professor Gill Wylie, gynecologist of Bellevue Hospital, to see the case. He said he thought there was cystic degeneration of the ovaries, and there was no hope but to remove the uterine appendages. He most decidedly advised the operation.

The young lady was not only anxious for the operation, but said to me more than once, "Now I want you to take out both ovaries, I don't want one left to give me trouble."[2] Another time she said: "I want both ovaries and both tubes removed. Such distress I have suffered for years—I am sore now from my arm-pits to my knees. I want both out, I don't fear the operation; I only dread the ether."

The operation was performed October 11, 1884. Every precaution had been taken as to perfect antisepsis "painfully careful." I had the father to secure large, airy, sunny rooms; no furniture except essentials, floors and walls washed with carbolized water. Sponges had been prepared according to the process described by Weir in the *New York Medical Journal*, modified by the method described by Pilcher in his work on "Treatment of Wounds." During the operation the sponges were kept in a solution of bichloride of mercury, 1 to 5,000. The instruments were placed in five per cent. carbolized water, reduced by hot water to two and a half per cent. just before the operation, according to a suggestion of Goodell's.[1] Two days before the operation the patient was placed upon an exclusive diet of pancreatized milk[2] to lessen the amount of gas in the intestines. The patient had daily evacuation of the bowels, and every day a hot bath followed by massage and inunctions of sweet oil.[3] Fritsch says: "I hold the procedure in which the uppermost layers of the epidermis are fully removed to be of great importance."

Not only were antiseptic vaginal injections used, but, what I regard as very important, disinfectant injections were thrown into the rectum; also I prescribed, just before the operation, two to five grammes of sodium salicylate, for I believe many times the wound is poisoned, and septic conditions induced from retained impurities in the bowels.

Just before the operation, the abdomen was washed off with soap and hot water, portions of it shaved, and the whole again washed off with an antiseptic solution, the umbilical depression wiped out with a solution of iodoform dissolved in ether, two drachms to one ounce. The pelvic organs had been held up with pledgets of cotton wet with a solution of alum and glycerine, a procedure much practised by Dr. Wylie for softening adhesions, and which I have used in many cases with most satisfactory results. The patient was in good spirits, cheerfully awaiting the operation. Ether was administered by Dr. Merritt. There were present Dr. Gill Wylie, Dr. J. H. H. Burge, and Dr. Charles N. Dixon Jones. I made an incision of two and a half inches opening into the peritoneal cavity. On account of the thickness of the abdominal walls, the incision was increased to three and one-fourth inches. I passed in two fingers, found the fundus uteri, and readily brought up the right ovary and right Fallopian tube; there were some adhesions and a few parovarian cysts. The ovary and tube were both diseased. I secured a pedicle, passed in Peaslee's needle armed with twisted Chinese silk, made a chain loop, and tied firmly. Dr. Wylie then held the pedicle with pressure forceps, just outside of the ligature, and I removed with scissors both ovary and tube.

The stump was touched with a drop of pure carbolic acid, and dropped. The left ovary and left Fallopian tube were somewhat more enlarged and more diseased than the right; the pedicle was secured, ligated in the same manner, both ovary and tube removed, and the stump treated as above. Very little blood was lost. The abdominal wound was closed with silver sutures, stitches passing from within outward, according to Goodell's suggestion in *The Medical Times*, which in this case was very important, on account of the thickness of the abdominal walls; for a needle to have passed from without successively through the cut edges of the abdominal walls, with the thick layers of fat, there would have been danger of the cut edges of the peritoneum and of other tissues not being nicely adjusted, or of union not taking place, or of the formation of a neural abscess. Silver sutures seemed very much preferable, not only in holding the cut edges of the thick abdominal walls firmly in apposition, but less likely to excite inflammatory action. At each extremity of the wound a superficial ligature was introduced, one of catgut, the other of silk; both

[1] Dr. F. Mundé reports a case of partial hemiplegia due to apparent sclerosis of spinal cord: he performed oophorectomy, and it was followed by rapid return of power of motion of the lower extremities, after eight years' inaction.

[2] Lawson Tait says: "I have never known a woman to submit herself to the operation without finding sufficient cause to justify its being done." Lecture in Jefferson Med. Col. Hospital: Medical News.

[1] Med. Times. [2] Wylie.

[3] Professor James Hunter: Med. Journal.

caused some suppuration in their tract. The closing of the wound required a much longer time than all the rest of the operation, but I had the satisfaction of feeling that it was all right. After securing the stitches, the wound was dusted with iodoform, then was placed immediately over it a small piece of Lister's oil-silk protective, after which I laid on several layers of wet corrosive sublimate gauze, then several layers of borated cotton, on which was placed a layer of McIntosh's thin adhesive strips, and the whole surrounded with a flannel binder.

The patient was placed in bed, covered with woollen blankets, and bottles of hot water placed to her feet and limbs. She recovered pleasantly from ether. As soon as she opened her eyes, her only question was to know if both ovaries and tubes had been removed. When assured that they were, she replied, "Well, I am satisfied."

The ordinary temperature of this patient before the operation was 99°, 99½°, or 100° F. On the eighth day after the operation, it was normal, which it had not before been for months or years.

The first twenty-four hours after the operation, the patient took only cracked ice, to which was added a few drops of brandy. On the second, third, and fourth days she took pancreatized milk, and some Vichy water; fifth day, beef-juice and beef-tea; eighth day, sandwiches of raw beef and Irish moss gruel. Her digestion seemed good; she had a good appetite, and her bowels moved pleasantly. The stitches were removed the eighth day; wound perfectly healed, and the abdominal wall seemed firm and strong.

On the second day after the operation she commenced to menstruate; no pain or distress. Antiseptic vaginal douches were administered. At the end of four weeks she had all the symptoms of a return of menstruation, accompanied by some nervous excitement and repeated chills, but no flow of blood.

The first two weeks after the operation she was cared for by an excellent nurse of the Brooklyn Training-school for Nurses. After this she was mostly nursed and surrounded by members of her own family, which was extremely unfortunate and very much against the patient's welfare. But notwithstanding these adverse circumstances, the patient seemed to gain, her nervous system seemed to grow more healthful. I could at times see a placidity and quietness of mental conditions which I had not before observed. She had some hysteria and nervousness, yet she was manifestly on the straight road to improvement and returning health, and in time, with proper care, would be entirely well. On November 19th, she had a severe attack of indigestion and great nervous excitement, owing to nervous people around and some family trouble, yet under these unfavorable circumstances her temperature was only 98⅘°. I believe if she had continued to have proper surroundings as she had at first, her improvement would have been very much more rapid. Still, it is not to be supposed that when these diseased structures have been for years a continued irritation and excitement to the nervous system, that as soon as removed the nervous system will immediately show healthful conditions. It will take time to recuperate, just as it takes time for the system to recuperate from any disease or sickness. Here was a sickness that had lasted for years, and when the cause was removed, could it be expected that she would immediately be well? Professor Wylie well said: "Impress upon the minds of the parents that it will take time, probably months, and years for her nervous system to become normal after such a long sickness."

A careful microscopical examination of the tubes and ovaries I made in Dr. Hulzman's laboratory and with his kind assistance.

The macroscopical appearance of the organs when removed: Ovaries were greatly enlarged, of a livid purplish hue; a number of cysts were apparent from the outside, one of which was much larger than the rest, constituting nearly one-third of the size of each ovary. Both of these large cysts were ruptured in handling. The tubes were greatly congested, distended in some portions, and from them could be squeezed out a quantity of brownish green pus, and muco-pus.

Microscopical examination.—Many of the Graafian follicles were distended and filled with a serous fluid, without a trace of ova, evidently in cystic degeneration. Vertical sections cut transversely through each ovary showed a marked hyperplasia of the arteries in the vicinity of the hilus, also in the medullary portion; they were also very much distended and had marked convolutions. The connective tissue in the neighborhood of the arteries was crowded with globular, partly homogeneous, partly granular inflammatory corpuscles, and the muscular fibre of the stroma was transformed into similar inflammatory corpuscles; impossible to trace unchanged smooth muscle fibres. Such inflammatory foci were scattered throughout the medullary substance of the ovary. Said Dr. Hulzman: These "morbid changes sufficiently explain the symptoms during the course of the disease. Both the chronic hyperæmia and augmented tissue elements account for the pressure upon the sensitive and trophic nerves, thus explaining the excruciating pain, and the reflex neuroses."

Transverse section of the tubes showed morbid changes: parenchymatous salpingitis, muscle-fibres pushed aside, and beds of inflammatory corpuscles, deep muscle fibres inflamed. The mucosa was thickened and thrown into deep transverse folds, blood-vessels and arteries increased in number, and inflammatory corpuscles most numerous in their vicinity. The lining of columnar epithelia was most entirely missing, and there was almost entire destruction of the ciliated epithelia which line the tubes; in a few places where these cilia were still adherent, they were prolonged, some of them club-shaped and all of them showing granular thickening.

From the microscopical examination of these structures, we see, first, that there must have been for a long time chronic ovaritis, and some salpingeal inflammation; second, that the disease of the tubes was manifestly extending and increasing, and, third, there was no possibility of the ovaries or the tubes ever being restored to health. Consequently, the only hope of the patient was the removal of these uterine appendages.

We see also that this young woman had been, from these hopelessly diseased organs, suffering for years the greatest physical pain and disability, not able to do anything; constant distress, irritability and sensitiveness, and her nervous system becoming more and more abnormal. Naturally of a clear intellect, yet she was at times listless, and subject to the greatest depression. More than once she contemplated suicide, said very significantly, if she did not get well she was going to die; that she could not continue to live as she then was.

It would have been better for her general welfare, health, and condition of her nervous system, if these diseased structures had been removed two or three years before they were. Had they been then removed, less damage would have been done to the nervous system, and she would have recovered more quickly and easily healthful conditions, and her vital resources would not have been so much exhausted.

I can here repeat the same conclusions I drew from a case I reported in the *Journal of Obstetrics*, November, 1884.

1. This operation should have been performed on this patient two or three years before it was.

2. There was no other way to relieve her than by the operation.

3. The operation to her was not so great suffering, nor so much of a shock, nor so great a trial as was a week of her previous sickness.

A few weeks after the publication of the above-mentioned case in the *Journal of Obstetrics*, I received a letter from Mr. Lawson Tait, Birmingham, Eng., dated November 23, 1884, in which occurs the following sentence:

"I agree with your conclusions concerning it absolutely. That poor girl's life would have been saved had the operation been done months or perhaps years before you were courageous enough to undertake it. The whole gist of modern abdominal surgery lies in an earnest and continuous plea for early interference. There can be no doubt that the only regret about all such cases is that they are allowed to go on so long without operation."

ALCOHOLIC HYPERÆSTHESIA AND PARÆSTHESIA OF THE FEET.

By C. F. BARKER, M.D.,

FORT HAMILTON, N. Y.

As the various effects of alcohol, its treatment, causes, etc., are at present causing more or less discussion among the profession, I take the liberty of narrating the various features of these cases as they have presented themselves to me. It has been my good fortune to have been able to observe and treat many of them.

This affection does not, as a rule, occur to those who are in the habit of drinking periodically, but it is the steady imbiber, he who has habituated himself or herself to the use of stimulants for months and years. It has no choice as to age, attacking the young as well as the old. We find it appearing in the phlegmatic as often as in the nervous patient. Like many of the affections appearing in the inebriate, it usually is first noticed when the victim begins to lessen his or her amount of stimulants. This, however, does not always hold true, as you will find those in whom the disease has been complained of, while the sufferer was markedly under the influence of liquor, and again it sometimes attacks the patients while they are far advanced in convalescence. I have in mind a case where the symptoms did not show themselves for weeks after the gentleman had been without stimulants, and another where the invasion was apparent while the man was still continuing his debauch. In the latter case, the attending physician mistook the symptoms for those of rheumatism. Quality or class of liquors does not seem to have any special bearing as to the causation of the trouble. The premonitory symptoms are not the same in any two cases. In some the disease is first noticed by the patient on rising in the morning; the feeling as if they had had a bruise from stepping on a stone, or perhaps muscular twitchings may be the first inconvenience experienced by the patient. These disagreeable feelings wear away during the day, but gradually become more marked and troublesome. After the disease is fairly developed they are often obliged to remain in bed. They suffer from pains of varying degrees of severity. The intense pain lasts but a few days, while the milder forms continue for weeks. The patient is often unable to stand the weight of the bedclothes upon the troublesome parts, and to have the shoes and stockings on is impossible. At times the slightest touch is so painful that the physician is unable to examine the parts. The toes are of much annoyance to the patients, having, as they will say, the feeling of being drawn under the feet. This sensation is so marked that patients will ofttimes feel with their hands to satisfy themselves that they are really in proper position. The soles of the feet usually give much trouble and are last to yield to treatment. The feeling is as if pins and needles were sticking into them, or that heavy weights were fastened to their shoes. In the more severe cases, if you have an opportunity to watch these patients when they alight from their bed, you will observe that they move as one does when he is carefully feeling his way in the dark. They seem to be afraid to step out. When asked why they do not move their feet more naturally, they will tell you they are not sure that they will be able to stand on them if raised and put down in the ordinary manner.

At night more often than during the day they experience muscular twitchings and a sensation of burning (not like that produced by an electric current), but as if they were stepping on a hot stove, a disagreeable sense of heat. These various feelings cause them to lose sleep and quite often interfere with their appetite. For the same reason that they do not use their feet in walking, they are not able to go up and down stairs, without aid. To go up stairs is more difficult than to descend. In a case lately under my care the patient was troubled with pains, taking a serpentine course from the ankle to all parts of the foot. They would not follow the course of any nerve, but dart in this irregular manner from one point to another, causing the patient much distress. It is exceedingly rare to have these sensations extend above the middle of the belly of the gastrocnemius muscle.

I have heard of cases where this disease has been mistaken for rheumatism and the patient placed under treatment for that malady.

Under proper care and treatment these patients recover perfectly. The recovery is slow, depending greatly upon the condition of the patient. Relapses do not occur unless the patient returns to his old ways of dissipation, and then but little over-indulgence will cause a speedy return.

Various modes and measures have been tried and advanced for the treatment of this affection, and to enumerate them all in this article would occupy too much valuable room. Those which have proved most efficacious are electricity, massage, hot and cold water baths, moderate exercise, to those who are able to be about, and tonics.

There is no doubt but that electricity takes the first position in the treatment of this disease. Both galvanism and faradism have yielded excellent results, but for my own use, taking the experience which has been afforded me as a guide, I much prefer the faradic current, in strength varying according to the severity of the case. The little French instrument, "Gaiffe battery," has in some cases proved very useful, but as it is limited in its power it cannot be used in all cases. The amount of time employed at each sitting varies; usually, to commence with, from ten to fifteen minutes is as much as the patient will be able to bear, but as improvement takes place the sittings may be increased. After the patients have become accustomed to the sensations of the battery, they are anxious to have it applied, as relief is experienced which is very marked. If applied before bedtime it gives the subject a much better chance of having a good night's rest than when used in the morning.

Massage, to those who can bear the process, is found often of great service in giving relief.

Bathing the parts in hot or cold water, hot water usually being preferred, night and morning, has been found to relieve many where massage could not be practised. The temperature of the water should be that which is most agreeable to the patient.

As to the choice of drugs, that depends greatly upon the condition of the patient. The employment of the sulphate of quinine has met with most pleasing results in my hands, and its value, I think, will be found by those who will try it. Pil. phos. ferri, quinia et strychnia has also been of much service. Nux vomica in the form of the tincture has also proved useful.

Much more could be written regarding this disease, but the foregoing may be a nucleus upon which to build. Advancing step by step as we are in the subject of inebriety and its complications, we may soon be able to diagnosticate and treat with equal certainty its many forms as we do the now classified diseases.

ACONITE is the perfect physiological remedy against neuralgia, especially when it is based upon congestive or sub-inflammatory trouble, but its action is often slow, so that morphine will have to be given with it, as a palliative, until great relief or a cure is effected. When there is a rheumatic element, colchicum may also be added.

TRAUMATIC LESIONS OF THE MEMBRANA TYMPANI.

By GORHAM BACON, M.D.,

AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY.

TRAUMATIC injuries of the drum-head are usually produced (1) by sudden condensation of the air in the external auditory canal or cavity of the middle ear; (2) by a fracture of the cranial bones extending to the membrana tympani; or, (3) by the penetration of some foreign body. Occasionally, the rapid rarefaction of the external atmosphere causes a rupture. Most frequently injuries of the membrana tympani occur in individuals who are in the habit of scratching the auditory canal with hair-pins, tooth-picks, etc., in order to relieve a disagreeable itching, and accidentally the instrument is pushed in too far; occasionally unskilful attempts to extract a foreign body from the external meatus result in the total destruction of the membrane, with severe inflammation of the auditory canal. Other causes are the instillation of strong solutions into the canal, boxing the ears, diving, striking of the waves against the ear while bathing, blows, discharge of cannon, gunshot wounds, kick on the mastoid process, and hanging. Frequently the drum-head is ruptured during attacks of violent sneezing and in whooping-cough.

In most all of the cases of rupture of the membrana tympani due to the sudden condensation or rarefaction of air or from blows, falls, etc., an examination of the ears will show a catarrhal condition of the middle ear with more or less obstruction to the entrance of air through the Eustachian tube or some calcareous deposit or other change in the membrana tympani itself.

In direct injuries the most frequent point of rupture, according to Zaufal, who has made experiments on the dead body, is in the anterior half of the membrana tympani. Politzer's experience agrees with that of Zaufal and he accepts the latter's explanation that "the instrument in striking the drum-head slides off from the obliquely placed posterior portion of the membrane, and consequently it is less frequently injured than the anterior portion. In one of my cases, where the injury was due to direct penetration, the drum-head was perforated in the posterior superior quadrant. Immediately after an injury to the drum-membrane by a sharp-pointed instrument, the rupture will be found somewhat round, the edges of which are usually covered with a dark red blood, and frequently there is more or less in the canal. The shape and size of the perforation often cannot be made out, owing to the extent of the injury and amount of the extravasated blood. Usually in direct injuries inflammation of the membrana tympani and middle ear supervenes and suppuration takes place. In direct injuries the symptoms of rupture at the time of the occurrence are a loud report with a sharp pain, accompanied by vertigo, considerable tinnitus, and frequently fainting. The noises usually persist and the patient complains of a numb feeling in the ear and side of the head, which continues for some time.

Ruptures produced by rapid condensation of air in the external meatus are usually due to blows or falls on the ear or loud explosions. According to Politzer, the shape of the rupture in these cases is always gaping, so that the inner wall of the tympanic cavity can be seen. The perforation is generally round or oval, with the long axis of the oval parallel with the direction of the radiating fibres. According to this author the most frequent seat of rupture is in the posterior portion of the membrane. Usually there is but one rupture. When the rupture is occasioned by a blow or fall, there may be concussion of the labyrinth at the same time, with considerable deafness, diagnosed by means of the tuning-fork and it is in these cases that disturbances of hearing frequently remain after the rupture has healed, as well as in those cases where inflammation and suppuration have set in.

CASE I. *Perforation of the membrana tympani from the penetration of a pencil.*—Rudolph J——, German aged twenty-nine, bookbinder, consulted me January 15 1884, and gave the following history: This morning while putting a pencil into the right auditory canal to relieve the itching, somebody ran against him and the pencil was pushed in too far. There was no pain at the time, but he was immediately very dizzy and there was a noise like a drum, which has been present ever since; the dizziness lasted for about fifteen minutes, and when he sneezed he heard a whistle in the affected ear. There is some autophony. His general health is good, and he has never had any ear disease before; uvula enlarged as well as both tonsils, and he has chronic naso-pharyngeal catarrh. Hearing distance: watch, right ear, $\frac{1}{48}$; left ear, $\frac{3}{48}$. Examination of the right ear showed that the inner end of the canal is congested; perforation of the membrana tympani in its posterior superior quadrant and covered with a clot of blood. There is congestion of the drum-head around the perforation and involving half of the membrane; cone of light almost gone.

Left ear: Membrana tympani retracted, lustreless, and parchment-like; short process prominent, and cone of light very small.

CASE II. *Rupture of membrana tympani from a blow.*—John H——, aged fifty, Irish, 'longshoreman, came to me March 4, 1884. Says he has always been healthy but subject to catarrh. When a boy, had some trouble with the right ear, and a doctor applied leeches. Hearing has been good. No further trouble till last Thursday, when he was struck by a man's fist; he immediately thought his head was broken, and felt a sting in the left ear and side of the head; he also experienced a buzzing noise at the time, but now it is less. He occasionally has a little pain in the ear. At the present moment there is a noise like the roar of the sea, but it is not always present. His voice sounds unnatural to him. He hears a noise in his ear when he blows his nose, which has been present since the accident. Hearing distance: watch, $\frac{1}{4}$, for both ears. Tuning-fork on vertex cranii heard, when vibrating, louder in the left ear.

Examination.—Left membrana tympani, congested; perforation in posterior inferior quadrant oval-shaped, extending from near the umbo almost to the periphery of the membrane, and running parallel with the handle of the malleus; right membrana tympani parchment-like, short process prominent.

CASE III. *Probable rupture of the membrana tympani from a blow.*—Thomas L——, aged twenty-nine; truckman; September 19, 1882. Says that three weeks ago he received a blow on the back of his head, and just over the right mastoid process. He remained insensible for twenty-four hours. Had dizziness and a noise in the ear, especially when he pressed on the auricle or over the temporal region; has noticed no discharge till last Sunday, when there was some blood on his pillow. He has right facial paralysis; cannot whistle or close the eyelid. Has autophony and some deafness.

Examination.—Left membrana tympani somewhat opaque and retracted, otherwise normal in appearance. Right canal contains some brownish pus. Membrana tympani macerated, but no perforation whistle heard. At the time of the accident there was probably a rupture of the membrana tympani, followed by inflammation of the middle ear. Pulv. boracic. acid. was insufflated, and he was given pil. calcii sulphid., āā gr. $\frac{1}{10}$.

CASE IV. *Probable perforation of the membrana tympani from a blow.*—A. F—— ; Scotch; clerk; October 10, 1882. Last Friday night he was struck across the left side of his head. He immediately felt a noise in the left ear, followed by a numb feeling. This numbness has continued in the affected ear. He has some autophony, but no pain. Hearing distance: right ear, normal; left ear, he hears loud voice.

Examination.—Left membrana tympani very much congested, purplish color. Some clotted blood in the canal and over the lower portion of the membrane.

Case V. *Fracture of the base of the skull; perforation of the membrana tympani.*—John E——, aged sixteen; July 29, 1884. Five weeks before, patient had all the symptoms of fracture of the base of the skull, with bleeding from the right ear, nose, and mouth, and double facial paralysis. The latter has disappeared. He was treated at the New York Hospital in June and July, 1884. Since then he has been deaf, and there has been a purulent discharge from the right ear. No earache lately, and for the past few days no discharge. Hearing distance: watch, left ear, $\frac{5}{48}$; right ear, $\frac{1}{48}$. Hearing not improved by Politzer's inflation; both Eustachian tubes pervious.

Examination.—Showed perforation of right membrana tympani. To take pil. calcii sulphid., āā gr. $\frac{1}{10}$; one four times daily.

August 7th.—No discharge since, although there is some pus at the bottom of the meatus. Hearing distance: watch, right ear, $\frac{4}{48}$; left ear, $\frac{6}{48}$. Pulv. acid. boracic. insufflated, and pil. calcii sulphid. continued.

Case VI.—Robert W——, aged thirteen; August 5, 1884. About two weeks ago he put a hair-pin in right ear, and "ran it in too far." About four days after, having had considerable pain in the ear for two days, the ear gathered and discharged serous matter and blood. Ear continued to discharge for a week and then stopped. For the last few days the pain has reappeared, and the ear began to discharge again, and this time pus appeared. Parts about the ear have swollen greatly; pain in the ear when swallowing.

Examination.—Right canal full of thin pus; canal swollen and tender; marked swelling and tenderness in the parotid region, upper cervical region, and some œdema, with slight tenderness over mastoid process. He was given pil. calcii sulphid., āā gr. $\frac{1}{10}$; one every three hours to be taken.

August 8th.—Has had no pain since; discharge slight; external swelling of the parts has disappeared; some thick pus at bottom of canal; middle ears inflated by Politzer's method, and pills continued.

August 12th.—There has been some return of the pain and swelling of the parts, with discharge from the ear. Ear bleeds from sides of the exterior meatus, and apparently from the membrana tympani. Politzer's inflation; pills continued. Pulv. zinc. oxid. et acid. boracic. insufflated.

August 15.—No pain since; discharge has ceased. At the bottom of the canal some pus mixed with the powder. Same treatment continued.

Case VII. *Injury to membrana tympani from an unsuccessful attempt to extract a foreign body.*—F. M——, aged three; May 2, 1882. Presented himself at the infirmary, and father said that the child had put something into his ear. He had taken him to a physician, who had made unsuccessful attempts to extract the foreign body with an instrument, but without any head-mirror. An examination showed that he had succeeded in lacerating the auditory canal, and probably destroying entirely the membrana tympani.

I have lost the records of a case where a patient applied to me at the New York Eye and Ear Infirmary, several years ago, and said that he had a severe earache several days before, when he applied to a neighboring druggist for advice. The latter kindly recommended him to pour St. Jacob's oil into the canal. He had done this, and succeeded in setting up a very severe inflammation of the middle-ear, with perforation of the membrana tympani.

Ordinary Drinking-water, says Neiquel, has from 58,000 to 106,000 bacteria per litre. On heating to 60° C. the algæ are killed. After boiling (100° C.) the water for fifteen minutes 99½ per cent. of the microorganisms are killed, leaving 500 germs per litre that are still living. A temperature of 110° C. or 115° C. kills these.

Progress of Medical Science.

Lumbar Nephrectomy.—At a recent meeting of the London Medico-Chirurgical Society, Mr. Henry Morris read a paper on this subject and related the history of a case in which he had performed the operation for renal calculus. The symptoms pointed strongly to the presence of a stone in the right kidney, and this organ was removed. After removal the stone could not be detected by palpation, nor even by pressing the kidney against a table, but on section it was found the size of a marble. The organ was healthy, except that it was somewhat harder than usual. Careful daily examination of the urine, before and after the operation, showed that the remaining kidney was very soon able to perform the work previously done by two. The patient made a good recovery. Most of the speakers who took part in the discussion agreed with the author in preferring the lumbar operation, though they admitted that the peritoneal operation was called for when the kidney was much enlarged. Mr. Knowsley Thornton alone advocated the peritoneal operation in all cases. He said that he would as soon wound the peritoneum as any other tissue—indeed, he would rather wound it than many of the other tissues.

The Etiology of Rickets.—The following are the conclusions of Dr. J. Comby, in an article on this subject in the *Archives Générales de Médecine* for March, 1885: 1. Improper feeding of the new-born is the sole cause of rickets. 2. By improper feeding is meant the giving of any aliment other than human milk during the first year of life. 3. Improper feeding also includes nursing when it is irregular or too frequent, or when the nurse is unhealthy. 4. The surest way to cause rachitis is to feed infants prematurely with meat, bread-pap, and other similar substances not made of milk. 5. Artificial feeding with a bottle and long tube is a very frequent cause of rickets; the employment of a bottle without a tube, or more simply, of a cup or glass, is less dangerous. 6. Supplementing the breast with the bottle, although better than artificial nursing, is not without its dangers. 7. Premature weaning, finally, is an active exciting cause of rachitis. Weaning should never be attempted during the first year, and should then be accomplished gradually and with discretion.

The Treatment of Popliteal Aneurisms.—In a paper in the *Archives Générales de Médecine* for March, 1885, Dr. Reymond Largeau advocates a return to the old method of treating popliteal aneurisms by ligature of both ends of the artery and opening of the sac. He relates the histories of twenty-four cases of this operation, collected from various sources, of which there were nineteen recoveries and nine deaths. Comparing these results with those obtained in other modes of treatment, compression, ligature of the femoral artery, etc., the author decides in favor of the old operation. He concludes that it should always be selected in traumatic aneurisms; in diffuse aneurisms on the point of rupturing, or when suppuration has occurred; and in circumscribed aneurisms, when compression has failed, without waiting for the tumor to attain a great size.

Fetid Animal Oil in the Treatment of Cholera.—Having observed that certain laborers, such as gravediggers, night-soil men, stable cleaners, etc., who come in contact with putrefactive processes, seem to escape cholera, Dr. Allegri (*Rivista Clinica*, January, 1885) proposes as a prophylactic fetid animal oil or Deppel's oil. This is prepared by dry distillation from animal matters, and was formerly used as a general excitant, diuretic, and diaphoretic, as an anthelmintic, and as an antispasmodic. The oil is to be given internally in capsule, and may be rubbed externally on the abdomen and extremities. It is to be feared that, after one trial of the remedy externally, most patients (and certainly their friends) would prefer to let the disease take its course.

Chancre of the Eyelids in Infants.—At the recent meeting of the French Ophthalmological Society M. Beaudry, of Lille, related a number of cases of indurated chancre of the eyelids in infants, caused by infection from the mother's saliva. Mothers were in the habit of moistening the crusts forming on the free borders of the lids with saliva, under the impression that this secretion was effectual in removing the morbid condition.—*Revue Médicale*, January 31, 1885.

The Use of Shishm Seed in Ophthalmic Practice.—This seed is derived from the *Cassia absus*, and has long been employed in Egypt in the treatment of the blennorrhagic ophthalmia so prevalent in that country. It was introduced into Europe in the early part of this century, and for awhile enjoyed quite a reputation in the treatment of inflammatory eye troubles. It was employed as a fine powder, either pure or mixed with an equal amount of sugar, or as an ointment. The infusion and decoction were regarded as of no efficacy. The shishm seeds enjoyed but a short-lived popularity, however, and were soon forgotten. Dr. Schuchardt has recently been studying the drug, and thinks that it gives promise of usefulness in ophthalmia, and he says that further investigations concerning its action upon the healthy and diseased conjunctiva are to be desired.—*Schmidt's Jahrbücher*, No. 7, 1884.

Treatment of Affections of the Respiratory Passages.—Dr. E. Lasniée recommends as of undoubted efficacy in the treatment of diseases of the lungs and respiratory passages a combination of beech-wood creosote, balsam of Tolu, and Norwegian tar. He gives it in capsules containing three-fourths of a grain of pure beech-wood creosote, and one grain each of balsam of Tolu and purified Norwegian tar. In mild cases of phthisis and as a prophylactic, two capsules morning and evening may suffice; and in graver cases the commencing dose may be four capsules morning and evening, increased gradually to twelve per diem. The capsules should always be followed by a draught of liquid of some sort, water, milk, wine or tea, which may be hot or cold as preferred. The best way is to take the capsules during a meal.—*L'Union Médicale*, February 1, 1885.

Copper in the Treatment of Scrofula.—Dr. Moulin has obtained good results with the various salts of copper in the treatment of scrofulous affections. He states that the cutaneous manifestations of this discrasia are relieved most quickly and certainly, and the ocular troubles, with the exception of keratitis, yield with almost equal readiness. The suppurative and indurated forms of adenitis due to scrofula are also frequently benefited in a marked degree by this metal.—*Rivista Clinica e Terapeutica*, March, 1885.

Cerebral Infantile Paralysis.—Dr. Strumpell has well described this somewhat neglected disease in an article of which the following is a condensed abstract (*Centralblatt für klinische Medicin*, January 31, 1885). Poliencephalitis acuta occurs usually before the end of the first year, sometimes indeed in the first weeks of life. It begins acutely without any apparent cause, with fever, vomiting, general convulsions, and unconsciousness. These symptoms disappear as quickly as they began, leaving behind them, as a rule, complete paralysis of one-half of the body, which soon, however, in part disappears. The arm and leg usually remain more or less paralyzed, while the facial muscles are restored, though sometimes there is slight strabismus. In other cases the paralysis is a monoplegia, or a sort of ataxia alone is perceptible. There is never any degenerative atrophy of the muscles, though the growth of the affected limb is retarded. The paralyzed limbs are slightly contracted, and there is an exaggerated tendon reflex. Most of the patients suffer from subsequent epileptic attacks, which may be general or affecting only the paralyzed side. Athetosis is a very frequent accompaniment. In right-sided paralysis the speech is not infrequently affected, and the patients are usually imbecile, though the intelligence may not be weakened. Sensation is unimpaired. The seat of the disease is in the gray cortical substance in the motor region, where in older cases parencephalic lesions are always found. No autopsies have yet been made in the acute stage of the affection. The author remarks on the resemblance to spinal infantile paralysis, and believes that the two affections may be due to the same or similar etiological factors.

Syphilitic Joint Diseases.—The following are the salient points of a paper by Dr. M. Schüller upon the articular manifestations of syphilis (*Schmidt's Jahrbücher*, No. 8, 1884). In acquired syphilis we meet with the following: 1. Acute serous inflammation occurring among the secondary lesions. This usually comes in connection with extensive skin eruptions, and generally involves several joints simultaneously. The lesion is a simple serous synovitis similar to that of acute rheumatism. This form is analogous to the pseudo-rheumatism met with in other infectious diseases. 2. Acute, or more frequently subacute or chronic, serous synovitis occurring at the tertiary period. Here we see a large serous effusion in a single joint. The capsule of the joint is thickened, and there is also a villous hypertrophy, sometimes with crepitation, but there is seldom any ulceration of the cartilages. The characteristic points are a comparatively great degree of pain and an arrest of the disease under antisyphilitic treatment, without, however, a restitution to the normal condition. The disease seldom goes on to suppuration. 3. Arthritis excited by the presence of gummata. The course of this affection is very characteristic. The gummy tumors are either in the immediate neighborhood of the joint or in parts of the joint itself. There is at first a thin, and later a thicker, gummy effusion. When the tumors gradually invade the joint a true gummy synovitis may arise, and in caseous degeneration of the gummata suppuration of the joint occurs. The subjective symptoms are very insignificant, and in no way correspond to the gravity of the joint lesion. The cartilage is the seat of sharply defined ulcers or of cicatrices. 4. Disease of the articulation arising from osteitis, periosteitis, or osteomyelitis of one of the bones entering into the formation of the joint.

In hereditary syphilis the following conditions may be found: 1. Subacute serous inflammation. The bones and cartilages are unaffected and suppuration may be absent, but there is an enormous serous effusion into the joint. The contrast between the very grave clinical symptoms and the insignificant anatomical changes is most striking. The author regards the affection as perfectly amenable to antisyphilitic treatment, provided suppuration have not occurred. 2. Inflammation due to the presence of gummy tumors. This differs in no way from the similar condition in acquired syphilis. 3. Arthritis arising from osteitis, periosteitis, and osteomyelitis of a neighboring long bone. This is not common. There is here a chronic serous effusion which progresses with varying subjective symptoms, but with an increasing difficulty of joint motion. Antisyphilitic treatment usually effects a complete cure. 4. Joint disease dependent upon a syphilitic affection of the epiphysis. This little known and seldom recognized condition begins with a sudden swelling of the epiphyseal periosteum. Serous effusion follows, at first thin and becoming thicker, the capsule is thickened, the joint becomes flexed, and is more or less painful. Fever is rare. In other cases there is a suppurative separation of the epiphyseal periosteum and an effusion of pus in the joint. The latter may come from the rupture of an abscess at the epiphyseal junction, and in such cases small sequestra may be found in the articulation. The cases of this disease which came under the author's observation were in children of three to four years of age.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 11, 1885.

THE SANITARY CONFERENCE AT NEW ORLEANS.

THE Sanitary Council of the Mississippi Valley recently held a meeting at New Orleans, which was of more than ordinary importance. This Council is composed of delegates from the several States lying in the territory embraced by the Mississippi River and its tributaries. The Council, therefore, represents a population of many millions of people, whose interests, however diversified in industrial pursuits, are one in all matters pertaining to the public health. This was the seventh annual meeting of the Council, and delegates were present from Illinois, Iowa, Kentucky, Louisiana, Michigan, Minnesota, Mississippi, Ohio, Tennessee, West Virginia, and Wisconsin. These delegates were representative men, and their opinions, as embodied in the report adopted, are worthy of the attention of all the Health Boards of the Valley. The official report of the proceedings is now before us, and we cannot refrain from noticing some of the more important acts of the Conference. Perhaps the most interesting feature of the proceedings is the evident harmony of feeling and unity of interest and purpose so essential to the successful organization and prosecution of sanitary measures covering a wide area of country. In previous meetings there has been a tone of distrust on the part of some of the delegates, especially of those from Louisiana, that has impaired the usefulness of the Council. But in his address of welcome, Dr. Joseph Holt, President of the Louisiana State Board of Health, gave utterance to the most generous sentiments. He welcomed the members of the Council to the rooms of the Board as friends and brethren.

"We do not tender" he said, "this as an obligation to the strangers within our gates, nor are we in the formal relation of host to guests, but as members of one family we greet you. Identity of purpose, unity of spirit, together with the relationship of States, have made us kith and kin. There is not a feature but is possessed in common by us and declares the family likeness. Most conspicuously we are the representatives not of ourselves, not of personal theories, caprices, petty aspirations, nor of some friends at home, but of that great unit the Mississippi Valley. We are the conservators of its public health, upon which the happiness and material prosperity of its teeming millions directly depend."

The Council has accomplished a great and much needed result in thus allaying all jealousies and uniting the health authorities of the entire Valley in common efforts against common foes.

In his annual report the Secretary, Dr. John H. Rauch, of Illinois, outlined the measures that should be adopted in the event of the appearance of cholera in this country as follows: 1. Prompt notification of outbreak; 2, local treatment of outbreak; 3, supervision of travel from the infected point. The Committee appointed to report measures necessary to prevent the introduction of cholera, and yellow fever into the Mississippi Valley, define quarantine to mean observation and sanitation.

We should add inspection before observation for a complete definition of the modern quarantine. Time is no longer a fixed element in quarantine, but is only a relative term. The most rigid quarantine need scarcely obstruct travel and commerce. If ship sanitation was as thorough as it ought to be at the port of departure, at sea, and at the port of arrival, detention at quarantine would be reduced to a minimum of time as unimportant as that required in shipping cargo, or taking on passengers. The committee very justly remark:

"The best method of quarantine should begin its work at the port of departure and be completed at the port of entry, to include approved methods of ship sanitation under competent authority, pending the voyage of a vessel from one port to another. The hazards of importation of infectious diseases would certainly be immensely reduced it there could be a guarantee that all vessels loading in foreign countries for ports in the United States are thoroughly cleansed and rendered non-infected before receiving their cargoes. Such a system of international sanitation, by preventing the shipment and exportation of disease, would insure safety and promote commerce."

If such a system were rigidly carried out, and every vessel had an honest bill of health, and a daily record of ship sanitation which the health officers at quarantine could examine and fully rely on, he could perform all his duties without even bringing the vessel to anchor in the great majority of instances.

Another recommendation of the Committee is of vital importance in the regulation of quarantine—viz., that an infected vessel shall not be allowed to reach the mainland. It states:

"If, however, an infected vessel, or one suspected to be infected, enters the Mississippi River, the State Board of Health of Louisiana should remand such vessel to a station of detention and absolute isolation until all danger of the spread of the disease from ship, cargo, crew, and passengers has been entirely removed; the ship to be thoroughly cleansed and disinfected; the cargo and baggage thoroughly disinfected, and the crew and passengers kept under observation until free from all suspicion of danger to the public health."

It has always been regarded as a great hardship by masters and owners of infected vessels that their ships must be subjected to such detention as is proposed by the Committee. But the wrong perpetrated is not by quarantine against the master of the vessel, but by the master against the public health of the port which he seeks to enter with his infected ship. The master of a vessel knowingly bearing the germs of pestilence from an infected port to a healthy port, is more guilty than a

pirate or an incendiary. He should not only be debarred from entering a port, but he should be placed under arrest for one of the gravest crimes in the calendar of criminal acts.

The Committee urge with great force the necessity for the immediate co-operation of the National Government with State Boards of Health in the enforcement of preventive measures against cholera and yellow fever through the medium of the National Board of Health. As enlightened and conscientious representatives of the great public health interests of the vast population of the Mississippi Valley, they have wisely forecast the measures of prevention of the threatening pestilences of cholera and yellow fever, and now petition the Government to perform its part in this national service.

CANCER-CURERS AND CANCER-CURES.

It is not strange that a disease so distressing as cancer should have stimulated the liveliest activity in the search for a cure. In the Surgeon-General's Index Catalogue we find nearly four hundred references to the treatment alone of cancer, while many pages are taken up with references to studies of other phases of the disease.

The discovery of "cancer-cures" began in the last century and has been pursued with unremitting industry to the present day. Pretenders to the possession of a specific can even now get wealth by liberally advertising in religious weeklies; but fifty and one hundred years ago they got fame and honor also. The cancer-curers have been the most numerous of all quacks.

In the latter part of the eighteenth century there were two famous men of this class in London, named Plunkett and Guy. They "cured" cancer by the application of a paste, known as Plunkett's poultice. Lord Bolingbroke, who had a cancer of the face, was one of the victims, his death being hastened by this poultice. Plunkett, who seems to have himself believed in his remedy, finally published the formula, which is as follows: ℞. Crow's-foot, 1 handful, dog fennel, 3 sprigs, well pounded; crude brimstone, 3 middling thimblefuls; white arsenic, same quantity. Mix, make into balls the size of a nutmeg, and dry in the sun.

The successors in London to Plunkett and Guy were Dr. Pattison and Dr. Fell, men who, we are sorry to say, flourished as doctors by virtue of American diplomas. These men also used an external application, the basis of which was chloride of zinc. To this, Dr. Fell added sanguinaria. During this period a specific known as "Lord Arundel's cancer-cure" was also extensively used. It consisted of a corrosive sublimate wash and an arsenical powder. In 1857 Mr. Spencer Wells showed the inutility of the methods of a clerical cancer-curer known as the Rev. Mr. Reed. This gentleman made large sums of money by his pretended remedy, which seems to have consisted mainly in the forcing of chlorine gas against the tumor.

But the prince of cancer-curers of all ages was Landolfi, of Naples. Flourishing about thirty or forty years ago, he practised his method not only throughout Italy, but in Paris, Vienna, and other capitals of Europe. He was knighted by the Italian Government, and received the order of the Red Eagle from Prussia. He claimed to have cured 3,000 out of 4,000 cases, a Prince of Prussia and the Duchess of Anhalt-Cothen being among his grateful patients. He used chiefly a substance known as "Landolfi's paste," which had the following composition: ℞. Zinci. chlorid., bromini chlorid., auri chlorid., antimon., chlorid., āā. M.

After the paste had destroyed the tumor he applied lettuce poultices. He also gave the bromine chloride internally. It must be said of Landolfi, as of some other cancer-quacks, that he apparently believed in his remedy, and showed a willingness to have the Faculty try its efficacy. When careful tests were made, however, it was shown to have only such good effects as belong to other caustic applications.

Turning now to the efforts of regular physicians to find some remedy for cancer, we find that the juice of the hemlock, belladonna leaves, pokeweed, pulv. verrucæ equinæ, and strangle-weed, were in the last century credited with wonderful curative powers. In late years the use of pokeweed (phytolacca) and hemlock has been revived. The virtues of arsenic and zinc were known long before the London cancer-quacks utilized them. In the history of cancer therapeutics for the present century we find a long and curious list of drugs and other measures that have been put forward as specifics. Sarsaparilla, fucus helminthocorton, juice of mancenillier, thuya occidentalis (arbor vitæ), smilax, ergotine, tar, house-leek, pipsissewa, cundurango, Chian turpentine, are among the vegetable remedies recommended for internal and external use. Arsenic, aluminium, iodine, the bromides, sulphur, iron, corrosive sublimate; acetic, citric, and carbolic acids; choral, chromic acid, the zinc salts and caustic potash have all had their virtues extolled.

Among methods of cure, the congelation process of Arnott deserves commendation. Rubbing, friction, and compression are useful measures in some forms of cancer. Boyle reports seventy-one cases out of one hundred and twenty-seven cured by compression. Carrot poultices, introduced by Sultzer in 1760, and revived by Marsden, are spoken well of by some authorities. The use of either the carbonate or oxyphosphate of iron, the internal and external use of arsenic, the injection of acetic acid according to the method of Broadbent, are among the measures best recognized as of utility in the treatment of cancer. Mr. Spencer Wells believes that bromide of potassium and cod-liver oil are the two best things to be employed, but he also speaks highly of iodine, iron, and especially of the iodide of arsenic.

Dr. H. G. Bowditch in 1849 reported a case of cancer cured by a bread-and-milk diet. Dr. Peirce in 1831 argued that a diet of Indian corn, with repeated excision was the best treatment. Dr. D. Brainerd (1852) gave lactate of iron by the mouth and injected solutions of it into the veins. Thiry in 1851 proposed syphilization of the cancerous mass as a means of destroying it. The direct application of gastric juice and the use of electricity are measures that have been temporarily popular.

Despite all, we are no nearer curing cancer than we were one hundred years ago. We can postpone death, relieve suffering, and make life more tolerable. In a small per cent. of cases the use of the knife removes the

disease permanently, and to the knife belongs, so far, the chief triumphs in the therapeutics of carcinoma.

Cancer is a diathetic disease, and a specific for it will probably never be found. The best hopes for the future lie in discovering the causes of the development of the dread disease and in preventing its appearance.

Meanwhile cancer-quacks will thrive, because man wants to live, because hope will not die, and because the diagnosis of cancerous from other tumors is not always easy. Most cases of ulcerating "cancers" cured by quacks have been cases of syphilis, while the other "cures" are cases of non-malignant tumor.

HIGH BUILDINGS AND PUBLIC HEALTH.

The Cities Committee of the Assembly and Senate of this State has been much occupied with the consideration of a bill providing that the height of all dwelling-houses hereafter to be erected in New York shall be regulated in proportion to the width of the streets. They shall not be higher than seventy feet in streets of a width of sixty feet, and not higher than eighty feet in streets exceeding sixty feet in width.

This bill is being opposed by certain builders and manufacturers, and strongly urged by other gentlemen. Professor C. F. Chandler states: "I consider these very high buildings a menace to the public health, and a great outrage on the rights of neighbors. The more families you put into one house the greater the danger from contagious diseases. It is almost impossible to properly isolate cases of scarlet fever, measles, etc., in these enormous apartment-houses. Another objection is the great danger from fire, and the difficulty which the great height offers to the escape of the inmates; but one of the strongest objections to them is the fact that they entirely cut off the sunshine from ordinary houses so situated as to be entirely overshadowed by them. Nothing is more necessary to health in the dwelling-house, especially for children, than sunshine, and some of these high buildings, particularly when two or three of them are clustered together, absolutely prevent all access of sunshine to certain dwelling-houses situated at the west or north of them." Most of these objections apply excellently to tenement-houses, but hardly to the high apartment-houses. Against the latter Dr. S. O. Vander Poel and others have urged that their sewage gutted the sewers and thus caused annoyances that were felt by the whole neighborhood; that tremendous draughts were created in their interior, siphoning out the pipes and the traps, and thus endangering the health of occupants. Sworn statements of responsible officers of the Fire Department have been submitted, showing that seventy-five feet is a limit beyond which the firemen cannot reach with their apparatus with any prospect either of saving life or of successfully fighting the flames.

On the other hand, several New York physicians have signed the following: "The undersigned physicians of the city of New York are of the opinion that the sanitary arrangements of the modern buildings known as apartment-houses are equal or superior to those of houses generally in the city of New York, and that houses with elevators have not only proved to be a great convenience, but of material benefit to both men and women afflicted with diseases which are aggravated by going up and down stairs. We are also of the opinion that any statements made to the effect that the erection of tall apartment-houses has materially injured, or is likely to materially injure, the health of the public, by obstructing the sunlight, and thus fostering malarial and other diseases, are largely fanciful and not justified by the facts."

There can be no question that high apartment-houses have in them serious elements of danger to health. It is possible, however, to reduce these dangers to a minimum by regulation of site, by thorough plumbing, etc. It is also to be borne in mind that the air at the height of the upper stories has been shown to be purer and healthier.

The erection of high apartment-houses need not be absolutely forbidden, but their construction should be most carefully regulated.

THE INHALATION AND INJECTION OF BLOOD.

It would truly be a great help in therapeutics if the functions of the stomach could be temporarily transferred to the lungs, or those of the lungs to the intestinal tract, thereby giving the affected organs rest. Professor S. Fubini, of Palermo, has been working in this direction, testing the capacity for vicarious action of the lungs. Obtaining a mixture of 20 parts defibrinated ox-blood and 80 parts of a three-fourths per cent. solution of common salt, he caused it to be inhaled by means of a double-bulb spray. No irritation was caused, and Fubini claims that the effects upon anæmic patients were instantaneous and striking. In cases of oligæmia, repeated inhalations of blood produced rapid improvement, as evidenced by the ordinary signs, and as tested by examining the blood with the hæmatocytometer and chromocytometer.

Professor von Ziemssen, of Münich, has recently brought forward claims for the therapeutic value of subcutaneous injection of human blood. After much experiment, he found that the injection of the blood of other animals was attended with unpleasant symptoms and did no good. On the other hand, the subcutaneous use of human blood in doses of 25 to 50 cubic centimetres, repeated a few times, exercised a pronounced and beneficial effect upon the quality of the patient's blood and the general condition.

A man forty years old, suffering for six weeks from scorbutus, and having a high grade of anæmia with hemorrhages, etc., received an injection of 50 ctm. of defibrinated human blood, in two doses. Next day the hæmaglobin amount had risen from 0.34873 to 0.47887 (normal being about 1.44000). Two days later this had fallen a little. He then received a second injection and on the following day the hæmaglobin amount was 0.49758. From this time on he improved so rapidly that further injections were not needed.

The blood used is drawn from the veins into a warm vessel and defibrinated. The most careful antiseptic precautions on the part of the operator are required. Finally, the blood must be directed toward the heart, and as it is injected, massage with the oiled hands must be actively used.

Professor Ziemssen's method of injecting blood produces similar results to those obtained sometimes by transfusion. He claims an advance, however, in that he has rejected the use of anything but human blood, and has devised a process which is simple and safe.

CHOLERA VACCINATION.

We find in *La Independencia Médica* of Barcelona, of March 1 and 11, 1885, the details of some interesting experiments by Dr. Ferrán relating to the personal prevention of cholera. Dr. Ferrán has been making a very exhaustive study into the natural history of the comma-bacillus, and it is claimed for him, by Dr. Sereñana and others of his disciples, that he has followed this microbe through all the phases of its existence, and has found it in certain periods of its evolution under forms never before described. But he has also been experimenting in the direction of the attenuation of the virus of cholera, in order, by inoculation with it, to produce a modified form of the disease which shall secure immunity for the subject from the graver scourge. It cannot be asserted that this object has as yet been obtained, nevertheless the results thus far observed are by no means such as to make the learned naturalist despair of success.

The first to submit himself to this somewhat hazardous experiment was Dr. Sereñana, who, on February 23d of the present year, received an injection into each arm of half a cubic centimetre of the attenuated virus. In less than three hours, he states, he began to experience severe pain in the posterior region of the arms, which gradually increased and rendered movement of the limbs difficult. At the end of seven hours he had a slight chill accompanied by a feeling of general languor, elevation of temperature, rapid pulse, insomnia, and headache. This condition remained for a little more than twenty-four hours, when there was a rapid abatement of all the symptoms, both local and general. Dr. Jacques was the second to receive the virus, and although he was injected in one arm only with half a cubic centimetre, his symptoms were even more pronounced than those of the first experimenter, and he also had slight cramps and nausea. Dr. Bertram, of Rubio, likewise submitted to the injection and experienced similar effects. An examination of the blood eighteen hours after inoculation, revealed the presence of micrococci, said by Ferrán to be the first form assumed by the comma-bacillus when injected into the living organism.

At the expiration of nine days two of these persons submitted to a reinoculation with negative results, while four others, who received primary inoculations with the same attenuated virus at this time, suffered from symptoms of considerable intensity. About two hours after the inoculation pain was felt in the arms, and toward evening, the injection having been practised shortly before noon, the temperature rose, the pulse increased in frequency, there were headache, languor, slight chills, and nausea. Later there was a rapid fall of temperature, and the hands and feet grew cold and presented a marbled appearance; at the same time the headache and nausea increased and were accompanied by complete anorexia. Some of the subjects had also slight cramps in the calves of the legs. In about fourty-eight hours all these symptoms had passed away. The highest temperature recorded was 102° F., and the pulse 125.

It must be confessed that these phenomena bear considerable resemblance to those of Asiatic cholera, and they are the more remarkable when it is remembered that an injection of the same virus, in identical dose, produced absolutely no results in two individuals who had been inoculated some days previously. These experiments must of course be repeated many times, and in presence of an actual epidemic of cholera, before they can be accepted as in any degree conclusive. But, if the cable reports truly, the disease has already reappeared in Spain, and Dr. Ferrán will now have an opportunity to put his experiments to the crucial test. In the presence of the unsatisfactory state of cholera therapeutics we can but hope, faintly though it may be, that a second Jenner has arisen in Spain, and that we may yet see cholera relegated to the position of small-pox, as no longer a scourge to be dreaded by civilized communities.

AN OFFICIAL OPINION OF THE PROBABILITIES OF AN EPIDEMIC OF CHOLERA.

The degree of knowledge of sanitary matters which now enlightens the General Government is frequently made public by newspaper-paragraphs. The latest utterance of "Surgeon-General Hamilton, of the Revenue Marine Hospital Service," to a reporter, was to the effect that, "with the single exception of Paris, the cholera did not spread in Europe beyond the places originally infected; that is to say, the south of France, certain Italian cities, and certain places in Spain bordering on the Mediterranean." The conclusion drawn from this statement is more remarkable than the statement itself, viz.: "Therefore, I am inclined to think that the present panic is unwarranted by any state of facts at present existing." Such ignorance of the recent epidemic, which spread consternation and death through Italian cities, and of the lessons which former epidemics have taught, is alarming as well as humiliating, for it represents the highest grade of intelligence which now governs the sanitary acts of the National Administration. It is now not surprising that, while every European nationality is making suitable preparations to protect its people from an invasion of cholera, and the State and municipal boards in this country are enforcing sanitary measures with great activity, our Government, with ample funds placed at its disposal, is literally doing nothing, either of itself or in aid of the health authorities. There will be no rational and intelligent action taken by the Government to prevent present or future epidemics, until the National Board of Health becomes in fact, as well as in name, the sole authority on which it relies for advice and counsel.

TYPHOID FEVER IN CHILDREN.

In an article upon "Typhoid Fever in Children," published in the "Archives of Pædiatrics," Dr. A. Jacobi gives the results of an analysis of twenty-five cases occurring in his wards in Bellevue Hospital. Of the twenty-five cases it may be said that approximately two-thirds ran a single course, one-fifth had a relapse, one-eighth were sick continuously for from four to six weeks, one fifth of the cases died. Roseola was observed in fourteen and diarrhœa in fifteen of the cases. The ages ranged from two to fourteen years, the average being nine.

Typhoid fever in children has not many strongly marked clinical features distinguishing it from that of adults. It appears, however, that in New York cases at

least, the roseola and diarrhœa may be absent, the bronchial symptoms mild, and the mortality of the disease less than in adults. The nervous symptoms, such as restlessness, or coma and delirium, are, in Dr. Jacobi's opinion, not prominent.

The local changes in the intestine are less marked than in the adult. In many cases the region of the ileocæcal valve only is affected, its redness being either dendritic or uniform; not often the colon, also, with the exception of its upper part, is in a condition of catarrhal congestion. The mucous membrane exhibits but rarely the peculiar infiltration so common in the adult. The ileum has but slight and superficial erosions; deep ulcerations are not frequent, in infancy they are but exceptional.

The mildness of the course of typhoid fever in children was attributed by Dr. Jacobi some years ago to the small number and size of Peyer's patches in early life. He now thinks that Gerhardt's theory is possibly correct, viz., that the infectious poison is taken in slowly through the lungs, instead of rapidly through the stomach and intestines. This hypothesis is a strained and fanciful one.

As for treatment, Dr. Jacobi speaks wisely. The main dangers, he says, arise from the elevation of temperature, the loss of blood, the diarrhœa, the insufficiency of nutrition—this insufficiency depending on the condition of the nervous system impaired by the poison, and injured digestion—finally the debilitated heart. "If the expectation method of treatment means, as it has frequently been understood, the letting alone of the disease, it is all right; if it means letting alone the patient, it is all wrong. It is not the disease we have to look after, but the sick."

To reduce high temperatures, quinia has not served him well in infectious diseases. A dose of from eight to ten grains (gramme 0.5 to 0.6) may be given during the remissions. It may be used internally or hypodermically. "Now and then injections into the rectum or suppositories are required or advisable when the stomach cannot be relied upon. The preparation to be used in the rectum must be one of those which are most soluble, the bisulphate, muriate, bromide, carbamide." No acid must enter the solution; large quantities of glycerine are objectionable. The rectal dose is to be at least fifty per cent. larger than that employed by the mouth.

"The internal administration is often hindered by the taste of the drug. Thirty parts of the compound known as elixir simplex cover the taste of one part of the sulphate, provided the mixture is made with each dose and not kept ready." Antipyrin has been used with quite good results; also salicylate of soda. But the best antipyretic is thought to be cold. Cold sponging and cold packs are used, and the rule prescribed is: "No cold bath for cold extremities; no more cold bath when once, after it, the extremities remain cold or cool."

As to whether antipyretics should be used at all we have these sensible words: "The question whether antipyretics ought to be employed at all, or how long, is answered by the general condition. As long as this is satisfactory, and particularly as long as the heart holds out, a febrile temperature harms but little. The common sense and ripe experience of the physician has to decide in every individual case, whether or no the heart requires strengthening or stimulation. As long as the pulse remains good, and not frequent, we need not hurry with either antipyretics or cardiac stimulants. The latter will often be more indicated than the former, and by improving the surface circulation will reduce the temperature also. In this sense digitalis and caffein are antipyretics. In some cases they may be combined to advantage with strychnia or ammonia, or camphor, and alcohol."

GENERAL GRANT'S CONDITION.

Although General Grant is, on the whole, much weaker than he was a week ago, his general condition is not so bad as many have been led to believe by the various sensational reports which have been circulated. He still manifests a remarkable vital power despite the temporary depressing effects of the recent hemorrhage. The latter was by no means considerable in amount, being scarcely four ounces. It appears to have had its origin by the exposure of a considerable granulating surface on the occasion of the spontaneous separation of a portion of the superficial sloughy patch on the right side of the vault of the pharynx. The bleeding ceased of its own accord, and has not recurred. As far as can be ascertained by any examination which the painful state of the parts will admit, the disease has apparently made very little progress within the past week. At least no signs of progressive ulceration are visible. There is no pain in swallowing, and the glandular enlargement under the angle of the jaw has not increased.

During the twenty-four hours succeeding the hemorrhage the pulse became more feeble, frequent, and intermittent, and the temperature at one time rose to 102°. In order to relieve pain and procure sleep the distinguished patient is kept mildly under the influence of morphine, the latter being injected hypodermically to the amount of six minims every six hours. A slight diarrhœa also existed during the period named.

The amount of nourishment taken is ample, and the powers of assimilation are reasonably active. Slight emaciation is noticeable, but no more than might be expected. The bodily vigor is in a great measure retained as the patient walks unaided to his basin, and stands during the act of gargling his throat. His intellect is clear, with the exception of a slight incoherency a few minutes after awakening from the morphine sleep.

The amount of bodily weakness, such as it is, bears no proportion to the extent of the local disease, but so far exceeds the latter that it is the serious matter in the element of prognosis. But, taken as a whole, even this condition, ruling out the possibility of heart-failure or the accident of another hemorrhage, does not necessarily militate against the probability of a prolongation of life for a number of days. Even as we write the pulse is inclined to become slower, with increase of volume, and his temperature has dropped to the normal line. Let us hope that the favorable indication may not be without significance.

ROLLER-SKATING AND LEUCORRHŒA IN GIRLS.

A correspondent of the *Boston Medical and Surgical Journal* writes that his attention was called to the existence of leucorrhœa in two young girls, aged respectively ten and twelve years. These girls had been in-

dulging excessively in roller-skating. Following up the inquiry, he found seven other cases of leucorrhœa in girls whose age ranged from nine to sixteen, all roller-skaters.

Excessive indulgence in roller-skating, especially at about the time of puberty, may very well be the cause of the trouble in question as well as of other disturbances. The *Journal* has wisely suggested that careful observations regarding the effect of roller-skating upon boys and girls be made by physicians and the results published. We shall be glad to hear from our readers upon the subject.

News of the Week.

The Symptoms Indicating Yellow Fever.—At the meeting of the Sanitary Council of the Mississippi Valley at New Orleans, March 10th and 11th, a committee reported the following as the "Groups of Symptoms Considered to Indicate Yellow Fever":

"I. Groups of symptoms which shall be considered to indicate yellow fever.—Group 1. A person, after a sudden attack, has a fever of one paroxysm, attended with marked congestion or blood stasis of capillaries of surface, conjunctivæ, and gums, with a history of probable exposure to infection, and no history of a previous attack of yellow fever. Group 2. A person, after a sudden attack, has a fever of one paroxysm, followed by unusual prostration, albuminous urine, yellowness of conjunctivæ and skin, and having no positively authenticated history of a previous attack of yellow fever. Group 3. A person has a fever of one paroxysm, albuminous urine, black vomit, suppression of urine, general hemorrhagic tendency, under circumstances where exposure to infection is a possibility.

"II. Suspicious cases of yellow fever.—The following symptoms associated with a fever of one paroxysm, in a patient who has apparently been exposed to infection, and has never had yellow fever, shall be held to justify in either of the six following cases a suspicion of this disease, viz.: 1. Suddenness of attack, either with violent pain in the head and back, injected eyes and face, or with marked congestion of the superficial capillaries. 2. Want of that correlation between pulse and temperature usual to other forms of fever. 3. Albuminous urine. 4. Black vomit. 5. General hemorrhagic tendency. 6. Yellowness of skin. The following cases shall also be deemed suspicious: 7. Any case respecting which reputable and experienced physicians disagree as to whether the disease is or is not yellow fever. 8. Any case respecting which efforts are made to conceal its existence, full history, and true nature."

Sickness in the Egyptian Army.—The pestilence is mightier than the sword. Gen. Lord Wolseley has sent to the War Office a significant report made out by the medical staff attached to the Khartoum expedition. The subject of this report is the result of the exposure to the desert heat of the British troops stationed along the borders of the Soudan desert. The report states that if the present British military station in the Soudan be maintained, fully one-half of the troops will die or be disabled by the heat before the arrival of autumn.

The Indiana State Medical Society will hold its annual session in Indianapolis on the second Tuesday in May, and will continue for three days. Let every physician of Indiana, who can possibly do so, be present.

Regulating Veterinary Practice.—A bill aiming to regulate veterinary practice in New York State is before the Assembly, and, it is reported, is likely to pass.

The Fairfield County Medical Society holds its ninety-fourth annual meeting at South Norwalk, Conn., on April 14th. An address will be given by the president, Dr. Seth Hill, and also one by Dr. Simon Baruch, of New York.

The Late Professor James L. Little, M.D.—At a meeting of the Faculty of the New York Post-graduate Medical School and Hospital, held April 5, 1885, the following resolutions were unanimously adopted:

Whereas, In the providence of Almighty God, our colleague and friend, James Lawrence Little, M.D., one of the founders of this school, has been removed from us by death. Therefore,

Resolved, That, in the death of Dr. Little, this institution, and our profession, have lost an accomplished and successful teacher and practitioner of surgery, and one who was also a wise counsellor in all the interests of the medical profession, and a firm friend and supporter of all efforts to advance its position.

Resolved, That we shall ever cherish the memory of his life, characterized as it was by scientific and philanthropic devotion to his calling, unblemished integrity, and genial relations with his associates.

Resolved, That a copy of these resolutions be signed by the officers of this school, and sent to The Medical Record and New York *Medical Journal* for publication.

(Signed) D. B. St. John Roosa, M.D., *President.*
Frederic R. Sturgis, M.D., *Secretary.*

Regarding the Adoption of the Term "Kollerism," a correspondent from Albany, N. Y., writes: "In your issue of March 7th, Dr. B. J. Baldwin proposes to introduce 'the words kollerization, kollerism, kollerized, as convenient terms to employ,' and adds: 'If the profession will adopt these words it will not only facilitate the expression of an idea, but their use will be a merited tribute to the fame of Dr. Koller.' Some word instead of cocaine and its proper derivatives would be indeed such a boon to the profession! To Dr. Baldwin and those in accord with him the following very sensible words of Dr. W. R. Gowers, London, are commended: 'This system of nomenclature is full of inconvenience, increasing the difficulties of the student, and leading to frequent mistakes in scientific writings. There are few observations in medicine regarding which it is not obvious that they would speedily have been made by some one other than the actual observer; that it was very much of an accident that they were made by certain individuals. Scientific nomenclature should be itself scientific, not founded upon accidents. However anxious we may be to honor individuals, we have no right to do so at the expense of the convenience of all future generations of learners.'"

American Medical Association.—The Illinois Central Railroad have arranged to run a special train of Pullman palace buffet sleeping-cars for the accommoda-

tion of delegates who wish to attend the meeting of the Association, which convenes in New Orleans April 28th and continues until May 1st. The special train will leave Chicago Saturday evening, April 25th, at 9 P.M., and run through to New Orleans without change of cars, reaching there at 9 A.M. Monday morning, April 27th, only thirty-six hours *en route*. The rates for the round-trip are as follows: Tickets good for return within fifteen days, $20; tickets good for return within forty days, $25; tickets good for return until June 1st, $30. Parties desiring to return another route, either via Louisville, Cincinnati, or St. Louis, will be provided with tickets at $5 in excess of above rates. Sleeping-car rates: From Chicago to New Orleans, one double berth, $6; from Chicago to New Orleans, one section, $12. Apply to C. S. Burton, ticket agent, 121 Randolph Street, Chicago, for berths.

TREATMENT OF CANCER.—A correspondent of the *British Medical Journal* advocates treating small cancerous tumors by arsenical paste, after a preliminary hypodermic injection of cocaine. He reports one case where this plan appears to have been efficacious.

THE CHOLERA WAR AGAIN.—A most important discussion over the significance and characters of Koch's cholera bacillus took place at the meeting of the Royal Medical and Surgical Society, on March 24th. Dr. Klein, who was present, showed his specimens and methods of culture. He made a strong argument against the contagionist view of cholera, and denied, as before, the specific character of the comma bacillus. Mr. Watson Cheyne defended Koch's view and gave illustrations of his own work. We can only say at present that while Dr. Klein made some very strong points against the view that the bacillus represents the virus of cholera, it was quite well shown, despite his evidence, that the comma bacillus is a specific micro-organism, always present in cholera.

Obituary.

PROF. JAMES LAWRENCE LITTLE, M.D.,

NEW YORK.

IT is with extreme regret that we have to announce that Dr. James Lawrence Little, Professor of Surgery in the New York Post-graduate Medical School, died very suddenly on April 4th, of peritonitis, following perforation of the appendix vermiformis.

Dr. Little was born in Brooklyn in 1836, and his professional education was obtained as a student under Dr. Willard Parker and at the College of Physicians and Surgeons of this city. He was graduated in March, 1860, having previously served six months as Junior Assistant Physician in Bellevue Hospital. Upon receiving his degree he was appointed *interne* of New York Hospital, where he remained for two years, and then became Surgeon-in-charge at the Park Barracks. In 1863 he was appointed Clinical Assistant to his old instructor, Dr. Parker, in the College of Physicians and Surgeons, and the following spring he delivered a course of lectures on fractures and their treatment.

Dr. Little delivered these lectures annually until 1868, when a regular Summer Faculty was formed, of which he was appointed Lecturer upon Operative Surgery and Surgical Dressings, a position which he held for more than ten years. In 1875 Dr. Little accepted the Chair of Surgery in the University of Vermont, and it was largely through his efforts that that college was made so successful. In 1882 Dr. Little assisted in organizing the New York Post-graduate Medical School, in which institution he was appointed Professor of Surgery. He earnestly identified himself with the interests of this school, and did much to promote its present prosperity. He was appointed Consulting Surgeon to the Northwestern Dispensary, Attending Surgeon to both St. Luke's and St. Vincent's Hospitals. He was a permanent member of the American Medical Association, and of the New York State Medical Society, a Fellow of the New York Academy of Medicine, and a member of the Pathological Society, the County Medical Society, the Northwestern Medical and Surgical Society, and of the *Medical Journal* Association. As an author Dr. Little's publications have been confined chiefly to medical journals. One of his most important papers, published in 1861, described a new method that has been generally adopted since, of using plaster-of-Paris splints for fractures. This paper was afterward considerably enlarged by the author, and republished and extensively circulated by the Sanitary Commission. One of his most important publications is "Median Lithotomy," a subject upon which he was considered a high authority, having performed the median operation more frequently than any other American surgeon then living. Probably his most brilliant surgical operation was the simultaneous ligation of the subclavian and carotid arteries of the right side, for aneurism of the first part of the subclavian, an account of which was published in the New York *Hospital Gazette*, in 1878. The feat has been accomplished in only fourteen instances in the history of surgery. He also had large experience in operating for hare-lip.

Among his other principal papers are to be found "Puncture of the Bladder by Dieulafoy's Aspirator," 1872; "An Excision of the Lower Jaw," 1873; "A Case of Naso-pharyngeal Tumor," 1876; "A Modification of Lister's Antiseptic Dressing," 1881; "Five Successful Cases of Tracheotomy for Croup," published in the London *Lancet*, 1883; "Operation for Restoration of Lips," 1883, and "A Case of Hypospadias," 1883.

Dr. Little was always a strong Republican in politics and opposed to slavery. In his early manhood he wrote a number of articles for the press on political subjects, and especially against slavery. On several occasions during the progress of the war he proved his willingness to go wherever the demands of patriotism or humanity called. After the second battle of Bull Run he proceeded to Washington, and offering his services to the Government was, with several other surgeons, assigned to the charge of the hospital for wounded temporarily erected in the National Capitol. At a subsequent period, acting in response to the call of the Governor of New York, he volunteered for service in the care and treatment of the wounded in the field, and went to White House, on the Pamunkey River. In the spring of 1864 a movement toward the sanitary reform of New York City was instituted by an organization known as the Citizens' Association, which appointed a number of sanitary inspectors to aid in carrying out its purposes. Dr. Little was among those thus appointed, and before the close of the year submitted an able report on the condition of the Twenty-first Sanitary Inspection District, of which he had charge. This report was embodied in the printed report of the Council of Hygiene of the Association above named, which led to the formation of the present Board of Health.

Dr. Little married, in 1858, Miss Elsie A. Charlotte, daughter of John Charlotte, Esq., of Newbern, N. C., subsequently a resident of Brooklyn, N. Y. For several years he has been a member of the Union League Club. As a lecturer and teacher Dr. Little was eminently practical and successful. As a man he was conscientious, faithful, of a genial and kindly manner, and greatly liked by all who knew him.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 3, 1885.

A. Jacobi, M.D., President, in the Chair.

The President read the by-laws concerning

ESSAYS AND PAPERS

read before the Academy, and stated that the publication of the Transactions would be resumed under the supervision of the Council. The third volume of the Transactions is now ready for sale.

The President also directed attention to

NOTORIETY BY THE NEWSPAPERS,

a point he believed to be sure to attract the earnest attention of the Academy, and to elicit the sympathy of every professional man who had at heart the dignity and morals of our calling. Dr. Jacobi further said: "When you elect a President you not only mean to confer a great honor upon him and give him great powers, but also grave responsibilities and urgent duties. Feeling as I do that you have placed me here for the performance of such duties, I invite your attention to the fact that membership in the medical brotherhoods imposes upon us certain obligations which no gentleman among us can possibly forego. I allude to the craving or obtaining, intentionally or otherwise, of newspaper notoriety. The rules of the Code of the American Medical Association forbid any form and manner of advertising through other than the strictly professional channels. That it has not succeeded in creating gentlemen out of men who have nothing but a diploma, a shingle, a carriage, and plenty of self-assertion, we all know. If it had done so, it would not have been abolished by a majority of the profession of the State of New York. If it had succeeded, there would not have been in so many instances so much advertising, openly and stealthily, in newspapers, under the circulars of proprietary medicines, and in other ways carefully avoided by the right-minded and high-souled men of the profession. The very fact that it did not succeed in preventing all that, was one of the reasons why the profession of the State was so ready to accept the teaching of the 'new code' movement. But the 'new code' movement, while insisting upon certain inalienable rights on the part of the individual physician, in cases in which the requirements of humanity impose duties of which no power can relieve him—even sanctioning consultations, in cases of emergencies, with persons who place themselves outside legitimate medicine by upholding sectarian names—has not done away with the moral teaching of the old code, so far as it gives expression to the conscience of the professional gentleman. Still high-minded sentiments, whole-souled convictions are not monopolized by either old code or new code. Indeed, the very men who favored the 'new code,' and those who went as far as to desire the abolition of all codes, did so for the very reason that the physician must be a professional gentleman, and not a tradesman.

"In this Academy I need not dwell upon the differences between the two. But it has so happened that of late several newspapers have been replete with sensational articles in large numbers on notable cases or operations. It must be admitted that it is almost impossible for a medical man to be kept out of the public prints. The reporter is everywhere. He has as many facilities to collect news as to distort them. Interviews cannot always be avoided, nor is it possible or perhaps advisable for a medical man, belonging as he does to a profession which is the natural teacher of the public in matters of public health, to withhold a reply to questions which can be answered in plain words of advice or instruction. But what can and must be avoided is the appearance in print of reports of striking operations or rare cases, which cannot possibly be of interest to the public at large, while they harm the professional man who is thus held up to public view, to be talked of in the morning, to be smiled over in the afternoon, to be forgotten with the new day.

"It must not enter my mind to say or believe that a gentleman whose demonstration of a new instrument was listened to by this New York Academy of Medicine, should be justly credited by a reporter of a newspaper with making the statement that 'there are hundreds of patients in our hospitals suffering from this kind of disease who are simply treated externally, because the city does not pay for surgical operations. They remain there for years until they die, but if this method of treating them proves successful, they can all be cured in a few weeks.'

"Such statements are simply inventions; no sane man could have known so little of the hospitals of the city, the surgeons attending them, or the nature of chronic bone diseases. I trust that no medical man anywhere has for a moment believed that such assertions could fall from the lips of a member of the regular profession, who is known to have a sufficient amount of both industry and ambition to make his mark without detraction of the efforts and services of others. But what I wish to urge is this, that our reputation and standing may be, after he is once called in or allowed inside, at the mercy of a lay reporter, whose capacity for understanding professional matters cannot amount to anything, as he has had no training for it, and whose principal object is to be interesting, though at the expense of his victim. Certainly a victim, for if there be anything less desirable than a stern investigation by a committee on ethics, it is to be held up to ridicule. If there be anything more certain than the futility of a temporary satisfaction to vanity obtained by a newspaper article, that would be the humiliation growing out of a derisive smile on the part of the profession.

"Why do I speak of the subject at all, and here? Simply because I have the interests of the Academy at heart, and feel deeply for the medical profession. Whenever I read glowing newspaper reports of cases, operations, and successes of a medical man, I cannot help both sympathizing with him and deploring the sensationalism of a report made by an outsider, as something which may prove derogatory to the dignity of the profession at large.

"This is what I feel as a member of that profession. As the President of this Academy of Medicine I claim the privilege of proclaiming those convictions which I was taught when I was young, and learned during my whole life to be those of the American medical profession."

Dr. Wm. H. Draper then read a paper on

ANTIPYRIN AND ITS EFFECTS,

beginning with the statement that, while progress in science had added but little to our knowledge of the essential cause of fever, it continued, from time to time, to enlarge our resources for its treatment.

After referring to the derivation of antipyrin, one of the many derivations from coal-tar, to its physiological effects as demonstrated by experiments on animals, and also to the fact that, while the poisonous dose in the human subject had not been determined, single doses of two decigrammes (about three grains) up to five years of age, and of two grammes (about thirty grains) in adults, should be given only when the patients were under constant observation, Dr. Draper gave a résumé of his experience in the use of the drug in the treatment of twenty cases of typhoid fever in the New York Hospital.

The majority of these cases were severe, seventeen occurring in males and three in females. The ages ranged from fifteen to thirty-five years. Five patients died and fifteen recovered. The ages of those who died ranged from eighteen to thirty years, and death occurred from the fifteenth to the fifty-fifth day.

The highest temperature in the fatal cases was 107.6 F. on the twenty-fourth day of the disease. The average

temperature of the fatal cases was 104° F., 102° F., 101.2° F., etc. In one of the fatal cases the temperature, under baths, remained at 104° F.; under antipyrin it fell to 101.2° F.

The highest temperature in the cases of recovery was 103° to 106.6° F.; the average from 100.6° F. to 103.6° F. Vomiting, in all the cases, was a frequent symptom in fifteen, diarrhœa was present in seven cases, constipation existed in eight cases, hemorrhage from the bowels occurred in two cases.

Antipyrin was given in maximum quantity of seventy-five grains, in three portions of thirty and fifteen grain doses at intervals of one hour. The pretty uniform result was reduction of temperature within three or four hours by gradual defervescence, and the depression continued from four to nine hours, usually attaining its maximum again in twelve hours. The *pulse* followed, approximatively, the temperature. No marked depression of the heart's action was noted, and cleaning and moistening of the tongue was one of the most marked and uniform effects. In one case seventy-five grains of antipyrin reduced the temperature to 93° F., but the reduction was not accompanied by any other signs of collapse. Generally the drug quieted the delirium, cleared the intelligence, diminished the deafness, and allayed restlessness and subsultus. In six cases it caused an erythematous rash, which gave rise to but little irritation and faded in the course of a few days, even though the remedy was not discontinued. The urine presented no other changes than those which accompany parenchymatous nephritis. The experience in the treatment of these cases confirmed that which had been claimed by foreign observers, namely, that antipyrin can only be commended as a sure and apparently safe means of reducing high temperature. It seemed idle to the reader of the paper to speculate as to how antipyrin reduced high temperature. It was not an antipyretic in the sense in which quinine and the salicylates were antipyretics, which neutralized the causes of the fever. Antipyrin smothered, but did not exterminate; however, it affected favorably all the phenomena of fever.

Dr. Draper believed that the only safe conclusions which could be drawn concerning antipyrin were the following:

First.—It is an efficient means of reducing temperature.

Second.—It is apparently a safe means of reducing temperature if prudently administered and carefully watched.

Third.—While it has not, so far as present experience demonstrates, markedly modified the progress or aborted diseases in which it has been administered, it contributes to the comfort of those suffering from high fever.

Fourth.—The unpleasant effects in some cases are more than counterbalanced by its advantages.

Fifth.—Future experience and modifications in methods of administration may so modify its effects that it may prove to be a precious contribution to the art of healing.

Dr. Corning spoke in favor of the theory that antipyrin produced its effect through the nervous system.

Dr. L. Weber continued the discussion (see The Medical Record, April 4, 1885, p. 373).

Dr. H. J. Boldt had used antipyrin in the treatment of two cases of puerperal septicæmia and also two cases of pneumonia, without obtaining reduction of temperature. The special effects which he noticed, the drug being given in doses of four grammes, were increased frequency of pulse with diminished strength, and intense prostration, the patient presenting the conditions seen in carbolic acid poisoning.

Dr. Kinnicutt had used antipyrin in his wards in St. Luke's Hospital, and in private practice, with quite similar results to those obtained and described by Dr. Draper. The list of cases embraced facial erysipelas with a high temperature curve, inflammatory rheumatism, pleurisy, pneumonia, scarlet fever, tuberculosis, typhoid fever, and a single case of intermittent fever. Gastric disturbance during its use had been exceptional in his experience, and in only one or two instances had he seen a chill occur. The latter symptom had been developed, as had been the experience with kairin, with a rising temperature following the minimum point reached. He had been particularly gratified with the certainty with which antipyrin controlled the usual afternoon or evening rise of temperature in phthisis. Its use had been believed to be contra-indicated in this disease, on account of the sweating which often accompanied its employment. In his experience, this symptom had been quite as often absent as present in such cases, during the administration of the drug. The curious phenomenon of a subnormal temperature, one of collapse, without other unpleasant symptoms mentioned by Dr. Draper, had been observed by him in a single instance. Twenty grains of antipyrin had been given in a case of pneumonia on the sixth day, with a temperature of 104°. The temperature at the expiration of three hours had fallen to 95° (in the mouth). The pulse, however, had improved in quality and diminished in frequency, and the patient had expressed herself as feeling excellently well. He had adopted the plan mentioned by Dr. Weber, of giving moderate doses of antipyrin, repeated two or three times in the course of the twenty-four hours, in cases of pneumonia and scarlet fever in children. He had found that by this method the temperature could be maintained within reasonable and safe limits. His dosage in such cases was a decigramme to each year of the child's age.

Dr. George L. Peabody believed that the lack of effect apparent in many cases was probably due to the adulteration of antipyrin. He had used it in the treatment of almost all febrile diseases, and, until recently, had succeeded in reducing the temperature in every case. According to his experience, no harm was done in ordinary cases by the administration of the drug, if the desired effect was not produced. It could be given hypodermically without causing local irritation or general evil effects, and it was freely soluble in hot water, so that the quantity could be readily regulated.

At present, however, all that could be claimed was a symptomatic effect, but that was such as to make it worthy of further trial.

Dr. Malcolm McLean referred to a case of chronic pyæmia following puerperal septicæmia, in which the cold bath, the cold coil, the salicylates, quinine, etc., were used thoroughly by Dr. Cox and himself, without affecting appreciably the temperature, which ranged between 103° and 104° F. After forty days' experience in the use of the above means, they resolved to try antipyrin, sixty grains daily, and the reduction of temperature to 100° and 101° F. was prompt and permanent during two weeks.

Dr. Draper, in closing the discussion, said that he had used antipyrin in a number of cases, according to the plan mentioned by Dr. Weber, and had given twenty grains twice a day, with very great comfort to the patients.

Dr. A. C. Post then described

AN ORIGINAL OPERATION FOR RUPTURED PERINEUM

as follows:

"The operation which I have devised for ruptured perineum has not been performed a sufficient number of times to entitle it to be regarded as an established operation. I have performed it but three times, but the result in each case has been so satisfactory as to induce me to commend it to the profession as worthy of further trial. The operation appears to me to be much simpler in execution than the operations which are ordinarily performed, and I think that it secures a more solid perineal body. It has also the advantage that there is no loss of substance in its performance, and if, from any cause, it should fail, it may be repeated with a good chance of success.

"The following is the mode of operating: An incision is made on each side of the fissure to the depth of fifteen or twenty millimetres. These incisions meet in front of the anus. They divide the parts into upper and lower segments. The upper segments are turned up to form the floor of the vagina, and are secured in position by a row of catgut sutures passed, not through the skin, but through the subcutaneous cellular tissue, so as to turn the edges of the skin upward in such a manner as to form a ridge on the floor of the vagina. A second row of sutures, composed of silver wire, is passed from side to side through the deepest part of the incisions, where the upper and lower segments meet; the ends of these sutures pass through glass beads and perforated shot, and when the flaps are brought into close contact, the shot are compressed with forceps, so as to keep the flaps approximated. The inferior segments then form a ridge on the perineum, and are secured by a row of fine silk sutures. When the parts have been well washed with a solution of mercuric bichloride, and dusted with iodoform, and a compress of iodoform gauze has been introduced into the vagina, the operation is completed. The integument at the inner side of the thigh should be protected from the pressure of the beads and shot.

"The patient should be allowed to urinate without the use of the catheter if she is able to do so. And, after each evacuation of the bladder, the parts should be washed with a solution of mercuric bichloride.

"The sutures may be removed at the end of ten days or of a fortnight."

Dr. Fanning, who had seen Dr. Post operate in two cases, said that the method seemed to be one that would prove serviceable.

Dr. Dawson thought that if all could be accomplished by the method which Dr. Post had mentioned, a great deal would be gained. At the same time, he thought the multiplicity of sutures, with the use of shot and glass beads was objectionable.

Dr. Post remarked that the deep row consisted of *three* silver-wire sutures, while the row on the floor of the vagina and also that on the perineum consisted of numerous catgut sutures.

The amendment to the by-laws, offered by Dr. Gibney at the last stated meeting, making provisions for the organization of

A NUMBER OF NEW SECTIONS,

was unanimously adopted.

The Academy then adjourned.

SECTION IN OBSTETRICS.

Stated Meeting, March 26, 1885.

Alexander S. Hunter, M.D., Chairman.

Dr. Malcolm McLean read a paper entitled,

THE MANAGEMENT OF PLACENTA PRÆVIA—AN IMPROVED METHOD BY WHICH TO COMPLETE THE FIRST STAGE OF LABOR IN SUCH CASES,

and exhibited some instruments, modifications of mechanical appliances already known, but which so simplified their application that the completion of the first stage of labor may be more promptly, easily, and safely accomplished by their use than by any other means at our command. The author regarded the views given by various authorities concerning the treatment of this complication as quite confusing, and the object of his paper was to suggest a line of treatment which was applicable to the great proportion of cases, and which gave the best chances for both mother and child.

The prominent feature of this grave complication of labor was the occurrence of hemorrhage, and all efforts must be directed toward its prevention.

The reader of the paper then mentioned the varieties of implantation, such as partial and complete, and also the conditions which present themselves in different cases, such as marked differences in the conditions of the tissues, notably the firm condition of the tissues in the primiparæ and the soft condition of the same in the multiparæ.

Of the various plans of treatment which had been recommended for the management of this inevitable hemorrhage, Dr. McLean only referred to those which deserved particular attention. First, the application of chemical styptics to the bleeding os; second, tamponing the vagina; third, the use of the vaginal tampon for completing the first stage of labor; fourth, rupture of the membranes and allowing the fœtal mass to press upon the bleeding surface; fifth, rupture of the membranes with rapid delivery; sixth, bimanual version, bringing down the feet; seventh, separation of the placenta, and either leaving the case to nature or delivery by version; eighth, plugging the vagina with Barnes' dilating rubber bags.

Dr. McLean thought the day had passed when chemical styptics, such as vinegar, alum, salts of iron, etc., should be applied to the bleeding os for the purpose of arresting hemorrhage. Posture and absolute rest should take the place of these local applications.

The vaginal tampon acted mechanically, and was the most valuable means we had. It was particularly valuable when the blood came from a firm cervix, and there was no indication for hastening the process of delivery. For such a tampon, there was nothing so good as carbolized wet cotton rolled into small balls, packed about the cervix, and filling the vagina full by the aid of a Sims speculum; the tamponing must be thoroughly done to be effective.

Tamponing the vagina and leaving it to be pushed out in front of the presenting part, according to Wiegand, was a plan of treatment which had been spoken favorably of by Hodge and others, and Dr. McLean wished to lay special emphasis on the advantage which this method possessed in primiparous cases. As serviceable as the method was, any condition demanding immediate interference called for some other method.

To the fourth plan, namely, rupture of the membranes and allowing the fœtal mass to press upon the bleeding parts, Dr. McLean offered some theoretical objections.

The method by rupture of the membranes and *accouchement forcè* he regarded as dangerous to both mother and child, and he could scarcely conceive of a case where such a procedure would be justifiable.

With reference to completing the separation of the placenta according to Simpson's method, he thought that, if cases occurred in which it seemed to be the most desirable way of management, the method should be confined to those in which there was a dead child or faulty pelvis.

In regard to Dr. Barnes' method and the use of the dilating bags, it was a most valuable method, and the dilators were one of the most valuable aids in the practice of our art. In cases in which the separation of the placenta had partially taken place, these dilators were invaluable.

Dr. McLean then exhibited a modification of the rubber bag, which consisted in a duplication of the bag and tube so that one side may be distended independently of the other, and required but one insertion; besides, the bag had no extra pocket on the outside. There need be only two sizes used, and he always used carbolized hot water for filling them. The bag was introduced by doubling it upon itself, seizing it with the curved jaws of a forceps which was devised especially for this purpose.

The conclusions to which the author of the paper arrived were substantially as follows: 1. In any case of placenta prævia avoid the application of chemical styptics. 2. Inasmuch as the dangers from hemorrhage were greater than all else, preparations to induce premature labor should be made. 3. In primiparous cases

with rigid tissues, the vagina should be well distended with the colpeurynter or tampon until cervical dilatation had taken place. 4. It was safer to rely upon thorough continuous pressure by Barnes' dilator than upon pressure by the fœtal parts. 5. Where the placenta was lateral or partial, and there was no indication for hastening the labor, the method of Braxton Hicks might be practised, consisting of turning by the bimanual method as soon as possible, pulling down a leg and with it and the breech of the child tamponing the ruptured placental vessels, and then letting the delivery be completed spontaneously, or aided by gentle traction. 6. When the head presented and the os was dilated, or very dilatable, rupture the membranes. 7. Podalic version was to be preferred to the application of forceps within the cervix, especially when the cervix was dry. 8. Complete vaginal tamponing might be applied and left in position in cases in which other means were not at hand. 9. The dangers of septic infection with the proper use of tampons and dilators was so slight that it need not be considered. 10. Wherever possible, delivery should be accomplished deliberately. 11. The greatest care must be exercised not to convey infectious material to the mother's system, which involved the application of the great principle of absolute cleanliness.

The discussion was opened by Dr. W. T. Lusk, who said the points in the paper were so fully in accord with his own belief, and had been made with so much judgment, that he had nothing to add by the way of criticism. He was much pleased with the double dilator and also the instrument devised by Dr. McLean. For some time he had been in the habit of using an ordinary pair of cotton forceps for the introduction of the dilating bags, but the instrument exhibited seemed to possess special advantages.

Notwithstanding his substantial indorsement of the views offered by the reader of the paper, he wished to say a few words with reference to the Braxton Hicks method advocated so strongly by Lomer. From statistics it appeared that in ninety-three cases in which this method had been adopted, there was only a single death —a result which certainly was extraordinary, and so extraordinary that it was worthy of most careful consideration.

Soon after looking over these statistics, Dr. Lusk was called to a case of placenta prævia occurring in the practice of Dr. Spaulding, of Harlem, and a day was finally appointed for beginning premature labor. On account of delay, over which the consultation had no control, the day for inducing premature labor was postponed, and when finally the day was reached on which it was to be begun, he was summoned before the hour appointed, and on arrival found that labor had begun spontaneously, and that the os externum was nearly completely dilated, with the internal os dilated to about the size of a silver half-dollar. Dr. Lusk at once prepared the patient, introduced his hand into the vagina, passed two fingers through the cervix, ruptured the membranes, pulled down an extremity, and version was completed, the whole operation probably occupying not more than two or three minutes. Then the breech was brought down into the cervix. Thus far, the dangers to the mother are almost nothing, and now the question arises concerning the life of the child, can it be saved? Although, of course, this is a secondary consideration, it is desirable to do so, if possible. In order to prevent hemorrhage, he found that it was necessary to make slight traction upon the breech, just sufficient to retain the child in contact with the surfaces from which hemorrhage might take place, and in a very short time the child was delivered alive. The patient was a multipara, which favored the accomplishment of labor with a living child, and the manipulations were practised with comparative ease; doubtless if the patient had been a primipara the difficulties would have been much greater than they were, but the method was eminently satisfactory.

The patient did well until two or three days later, when she died somewhat suddenly from pulmonary embolism, probably due to delay in the induction of premature labor. So far as checking the hemorrhage was concerned, he could not speak of the method in too high terms of commendation. The method of treatment, therefore, of placenta prævia, which he felt disposed to recommend, was to tampon the vagina if dilatation of the cervix has just begun, and, as soon as possible, introduce a Barnes' dilator into the cervix, and when the cervix was sufficiently dilated to render the extraction of the child a matter of no great danger, proceed to follow it up by the method of Braxton Hicks. He should hesitate very much before adopting the method by rupture of the membranes and trusting to uterine contractions to bring the head down.

Dr. Isaac E. Taylor thought that a distinction should be made in the treatment of placenta prævia between the cases of placenta centralis and cases of placenta lateralis, or partial prævia. The treatment of partial separation of the placenta was so simple that it required but little consideration.

With regard to placenta centralis, early delivery should be effected, for the patient's life was in great jeopardy. This was to be accomplished by dilatation of the neck of the womb and resorting to version, and version could be best accomplished by the bimanual method; that is, by the aid of external manipulations. The dilatation of the cervix might be accomplished by different means. When Barnes' dilators were used, or a vaginal tampon, dilatation or separation of the placenta did not take place at the internal os, but it excited contractions, and the placenta was partially separated when the external os was dilated to the size of a two-shilling piece. Nature had then done her work, and the case became one in which only partial separation was to be accomplished.

Out of fourteen cases of placenta centralis which had been under his care, only five deaths had occurred. In most of the cases of placenta centralis the children were lost, but that was a matter of but little moment as compared to the saving of the life of the mother.

Dr. Taylor remarked specially with reference to the situation of the placenta in placenta centralis, and said that he had established by ocular demonstration the fact that the placenta was not attached to any part of the cervical canal.

Dr. W. M. Polk said that after the concise paper by Dr. McLean, and the remarks made by Drs. Lusk and Taylor, there remained but very little which need be said upon the subject. He thought the point brought out by Dr. Taylor, namely, that of making a distinction between placenta centralis and partial attachment of the placenta, was an important and practical one, as there was a great difference in the management of these two classes of cases. The fact of the placenta being central added very much to the danger, both with reference to the mother and the child.

As far as the general management of these cases was concerned, it was practically that adopted by Dr. Taylor, and Dr. Polk believed that the vaginal tampon was the safest remedy which could be employed. The points suggested by Dr. McLean, that the ablest obstetrician would often find difficulty in introducing Barnes' dilators, was one which most obstetricians were willing at once to grant, and therefore any device which would facilitate the introduction of the dilating bags would be very acceptable. But it seemed to him that the wisest plan to be adopted was the simplest and safest plan for meeting the hemorrhage, and the tampon was probably the best way by which it could be arrested. He would suggest that the modification of the tampon by the use of the roller bandage would not fulfil the indications at all. He did not pretend to say that it had not done so in Dr. Taylor's skilful hands, but it must also be said there were but few who were equally skilled in obstetric manipulation. Dr. Polk recommended thorough tamponing of the vagina,

and by balls of cotton, tied together kite-tail fashion to facilitate removal, as the best and the most effectual method, and also introduced by the aid of Sims' speculum.

With regard to after-treatment, if the method of management advocated by Lomer was adopted, and the child was ignored, the management of these cases was comparatively simple, and certainly introduction of the hand into the vagina and through the nearly completely dilated cervix gave the accoucheur thorough control of the situation. With perforated membranes, version according to Braxton Hicks' method could be readily performed; then bringing down one leg, allowing the other leg and body to remain in the cavity of the uterus, such pressure was exerted upon the lower segment of the uterus as would completely control hemorrhage.

One would think that the child need not suffer materially in these cases, because the hemorrhage is arrested, and the extraction can be accomplished quite readily; but the statistics referred to by Dr. Lusk proved conclusively that the mortality to the child is very great.

The use of Barnes' dilator was unquestionably a measure of very great value in the milder cases, where the placenta is attached to the borders of the os, or a small portion overlaps the cervix, so that the hemorrhage will not probably last long. But where we have to deal with central implantation. Dr. Polk preferred to commence and continue with the tampon until the cervix was certainly dilated sufficiently to permit version.

Dr. Polk also sustained Dr. Taylor's opinion, that the placenta is not attached to any part within the cervical canal, and referred to museum specimens which illustrated that point.

Dr. E. L. Partridge referred to some of the clinical features of placenta prævia, of which he had seen quite a large number of cases, and in quite a proportion of them the placenta was centralis. He wished to commend the rubber bags in the management of placenta prævia of both forms, and he also spoke against the use of the tampon, especially with reference to the liability of conveying septic material to the mother; for, in very many instances at least, the material of which they were composed was such as rendered the liability of the induction of septic infection very great. He indorsed the view that the little pocket on the side of Barnes' dilator must be abandoned, and regarded Dr. McLean's instrument as a most excellent device for the introduction of the bags. With reference to the liability of hemorrhage to occur during the change of the ordinary Barnes dilators, the point which had been referred to by Dr. McLean, he believed that it did not constitute a serious objection to the use of Barnes' dilators, for he had used them in four cases of placenta prævia, and no hemorrhage had occurred in either of them during the period of the withdrawal of one bag and the insertion of another. The rubber bag goes directly to the source of hemorrhage, and was the most effectual means at our command, for controlling this hemorrhage, as had been brought out by the author of the paper, and this pressure should be continued until the cervix was dilated. According to his experience the further obstetric procedure had been by version, as recommended by the very large majority of obstetricians, and complete version—not the method advocated by Braxton Hicks. Dr. Partridge did not regard placenta prævia under ordinary circumstances as a serious complication of labor.

Dr. R. A. Murray was fully in accord with the remarks which had already been made, and would simply refer to the importance of distinguishing between lateral and central implantation, as the management of the two classes of cases was entirely different.

With regard to Barnes' dilators, he had used two side by side, sometimes three of the smaller size, when the larger ones were not at hand, and really had obtained the results mentioned by Dr. McLean. Dr. Murray, however regarded the instrument and the dilators exhibited by Dr. McLean as a very great improvement on the instrument and dilators which he had ordinarily used.

Dr. P. F. Mundé said he had nothing to add in the way of criticism on the excellent paper of the evening. He had seen twelve cases of placenta prævia, four of which were centralis, and the others partial prævia. Of these twelve women, only two died, and four children were born dead.

Dr. Mundé regarded the three cardinal points in the management of placenta prævia to be as follows: first, to arrest hemorrhage; second, dilatation of the cervical canal, and also of the soft parts sufficiently to allow easy manipulation, and then, third, rupture of the membranes and speedy extraction of the child, as rapidly as possible consistent with safety to the soft parts. He had usually employed the colpeurynter to accomplish dilatation, but any instrument which distended the upper part of the vagina was sufficient. If the cervical canal was dilated to the size of a silver half dollar, he thought that dilatation could be completed immediately, and delivery of the child accomplished at once, better than to turn and block the passages with the child, leaving nature to take care of the case. Although the life of the child was of secondary consideration, yet he thought that complete version and rapid delivery, as indicated, was equally safe for the mother, and that it would increase the chances of saving the life of the child.

Dr. W. E. Forest thought it important to first establish labor pains, and for this purpose the use of the colpeurynter or vaginal tampon was better than the use of Barnes' dilators; for the cervical canal might be thoroughly dilated, and yet no uterine contractions take place, and under such circumstances the condition of things was very unpleasant, not to say dangerous.

His plan of tamponing the vagina was by means of cotton balls soaked with soapsuds, which rendered it unnecessary to use a speculum, and he believed the vaginal canal could be thoroughly tamponed in this way. This tamponing was followed by pains which dilated the cervical canal, and when dilatation was sufficient the child could be easily turned by bringing down a foot, and the labor went on because the pains had already been established before the version was practised. If, however, the os was dilated rapidly, as by means of Barnes' dilators, there was no natural condition present for the subsequent process of labor.

Dr. McLean, in closing the discussion, said that if there was one thing which Barnes' dilators accomplished it was to produce uterine contractions quicker than could be done by any other method, and it was because of this that he urged their use. The colpeurynter would excite contractions, but not so quickly, and, besides, it was not known, when the vagina was distended with the colpeurynter, exactly how much dilatation of the cervical canal had been secured until the colpeurynter was removed, and then a gush of blood might come which did not follow dilatation with the rubber-bag.

The Section then adjourned.

The Present Drift of Gynecology.—One often hears, nowadays, that the uterus is a much-abused organ, but if that organ could speak for herself I think one would hear her say that she felt herself very much neglected, and that her neighbors, the ovaries, tubes and ligaments, were receiving all the attention. She is not credited now even with an independent catarrh. This will serve as a hint to the direction in which modern pelvic pathology is tending. One specialist of note here is known by his *confrères* as the "ovarian fisherman," for he usually finds an ovary that has strayed away from its *habitat*, thus disquieting the whole pelvic household. There seems to be a pretty general feeling against the use of pessaries except in a very few cases. The treatment for displacements is principally by vaginal tampons, medicated either with glycerine alone or with alum and glycerine.—*Correspondence Canada Medical and Surgical Journal.*

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. HERMANN WEBER'S CROONIAN LECTURES—THE COMMUNICABILITY OF PHTHISIS—ITS CURABILITY—DR. ROUTH'S REPLY TO DR. CLIFFORD ALLBUTT'S ATTACK ON THE GYNECOLOGISTS—NEW POISONS ACT—MEMORIAL HOSPITAL TO GENERAL GORDON AT PORT SAID.

London, March 23, 1885.

In his first Croonian lecture, Dr. Hermann Weber discussed at some length the questions of the infectiousness and contagiousness of phthisis. He remarked that he supposed we were all convinced that infection can take place by inoculation, and that this may possibly occur more frequently than is thought. Dr. Weber refers to some striking cases bearing on this point. He is an advocate for the view of the contagiousness of phthisis adopted by so many of our continental brethren, especially the Italian physicians. As a German physician settled in London, he is probably more *en rapport* with continental opinion than ordinary English physicians, though it is to be noted that Dr. Weber has somewhat modified the views expressed by him, ten years ago, in a paper on the subject read before the Clinical Society. He now acknowledges that cases in which phthisis has been communicated are rarer than then appeared to him, but states that he remains convinced of its communicability under certain circumstances, and urges the rigorous adoption of the hygienic precautions which this view renders desirable. In speaking of food, Dr. Weber said he quite agreed with Dr. Duckworth as to the insufficient use of milk as an article of diet in England, both by children and adults. Fresh air, sunshine, flannel underclothing, bathing, and exercise, were all pointed out as desirable. In speaking of ventilation, Dr. Weber mentioned the undeserved neglect which has fallen on Dr. Henry MacCormac's views, and said that whatever we might think of his explanation of the origin of consumption by the "breath rebreathed," we must acknowledge that pure air is the best way to prevent it, and that Dr. MacCormac has pleaded in favor of it more eloquently than any other author.

Another phase of the subject taken up by Dr. Hermann Weber was the question of the curability of phthisis. The prognosis of this disease is now generally regarded as more favorable than formerly. Most observant physicians have met with cases showing that some patients are able to throw off the malady, and numberless post-mortem records prove that a process of repair does take place and the patient is practically cured, although "lamed" so far as regards his lung-power. Dr. Weber related a case in which he had the opportunity of observing two separate attacks of phthisis in the same patient, from each of which he recovered. Dr. Weber says he found the remains of the lesion by post-mortem examination seven years after the second recovery, when death had occurred from typhoid fever with perforation. The question arises whether these two attacks were bacillary, and, if so, whether the encapsuled cretaceous and semi cretaceous masses still contained bacilli and spores. If bacilli and spores could live for years in such masses, it was possible that a fresh attack of phthisis, occurring in a patient after years of apparent cure, was in some cases due to self-infection from the escape of imperfectly shut-up parasites. It is interesting to note that Dr. Neuwerk, of Tübingen, has recently published a case tending to show this.

Dr. Clifford Allbutt's assault on the gynecologists provoked a good deal of comment at the time, and not a little angry feeling among the subjects of his animadversions. I am inclined to think a good deal of the latter arose from the "cap fitting" only too well. I suspect that most medical men, both in England and America, who have seen much practice, could narrate cases of patients who, while suffering from some local disorder really insignificant, have been persuaded by some unscrupulous specialist to go to him again and again (*and pay fees*) for the purpose of being examined, having caustic applied, and so on, until at last "the arrow of hypochondriasis is implanted." Of course, I do not mean to hint that every gynecologist is of this stamp, but there cannot be much doubt that such things have been. Uterine diseases cannot be treated without a diagnosis being made, and local examinations are necessary. I believe that most of the physicians in London who practise gynecology as a specialty, do so with all reasonable delicacy; but I believe there are a few who are quite as capable of applying caustics without need to the os uteri as of painting the uvula daily for weeks as a preparative to removing it! I have heard of the latter being done, but I would not have your readers infer that such is the usual practice of British practitioners.

At the last meeting of the Medical Society of London, Dr. Routh read a paper on "The Constitutional Treatment of Disease of the Uterus and its Appendages," in which he protested against Dr. Allbutt's views. In opposition to him, he maintained that general neuroses were not more common than uterine disease; that many cases of true disease of the uterus were overlooked, owing to imperfect methods of examination; and that the great advances made in the study of diseases of the female generative organs were due to the careful and systematic examinations conducted by gynecologists.

Dr. Allbutt, who had come up from Leeds to be present, replied, and said he felt Dr. Routh's criticism left him untouched. In the course of a long speech, he again put forward in an expanded form the views expressed by him in his Gulstonian lectures last year. It is impossible to epitomize his speech in a few lines, but I may just remark that one main line of argument he adopted was that, in cases of apparent uterine disease with neurotic symptoms, his view was that in many cases the neurosis was primary and the womb-mischief only secondary. If we merely treated the latter, we should fail to cure the patient. He would not deny that there were gynecologists who practised in a scientific spirit, but he knew that there were a large number of practitioners who treated cases of this kind from first to last as merely uterine. Dr. Allbutt concluded by saying that he did not wish to be classed as an obscurantist. He held very strongly that it was imperative, in certain cases, to make an examination of the sexual organs even in virgins.

The agitation for the repeal of the Patent Medicines Stamp Act is as yet unfruitful, but a new "Poisons Act" has just passed the second reading in the House of Lords, and may perhaps partly neutralize the evil caused by the Stamp Act. It renders more stringent the regulations for the sale of poisons, and the act is to apply to such patent medicines as can be proved to be poisonous.

The proposal for a memorial hospital to General Gordon, at Port Said is enthusiastically received, both within the profession and outside our ranks. Nearly all of the sum necessary has already been promised.

THE CHOLERA IN 1849.

To the Editor of The Medical Record.

Sir: During the epidemic of cholera in 1849 I was physician to the Seventh Ward, and I attended a large number of cases. As is usual in the early outbreak of nearly all epidemics, a great many of those attacked with the disease died, but toward the latter part of the epidemic, when the disease was not so rapid in its progress, I saw the good effects of the remedies used.

With all persons over whom I had control I compelled the use of water that had been boiled. I found I could do this better by extolling the virtues of black tea, so much so, that many of the drinking saloons kept hot tea

and I thus greatly reduced the use of spirits. Among this class of people I got the sobriquet of "Boiled Water." As much as possible I prohibited the use of crude uncooked foods, and induced people to use foods that had been subjected to fire.

As soon as I was called to a case of cholera, I administered five grains of tannin dissolved in a teaspoonful of sulphuric ether, and if there was much nervous irritation or fatigue this was accompanied with a dose of opium. I kept readily prepared the following mixture:

℞. Tannin..... ʒj. ɔj.
Sulphuric ether..... f ʒij.
Syrup simpl..... f ʒij.
M

This was shaken and a dessert-spoonful given at a dose, washed down with some sweet flax-seed tea.

I also kept readily prepared some very thick syrup of flax-seed; warm water added to some of this readily made flax-seed tea. This dose of tannin and ether was given every hour until the diarrhœa was controverted; occasionally it was necessary to give ten to twenty drops of laudanum, but opium alone was insufficient to check the diarrhœa. I have often seen a single dose of the tannin and ether check a profuse diarrhœa; then a full dose of laudanum in ether was given to keep the patient in the recumbent position for twelve hours or more. Often these doses of tannin and ether did not check the discharge, I then gave five grains of tannin and two drachms of ether in half a pint of warm milk as an injection, using a large catheter to throw it as far up the bowels as possible.

Tannin and ether afforded me better results than any other remedies; often I needed opium, but more as a sequence to keep the patient quiet after the effects of the tannin. Opium treatment alone gave me but little satisfaction.

During the month of August, 1849, I was conversing with Professor Joseph M. Smith upon the use of tannin. He said he had tried it without any good results, but he acknowledged that he had used it only in one-fourth grain doses. He said he should be afraid to give it in five and ten grain doses, as I had done, fearing it would be poisonous, but he afterward saw a patient with me to whom we administered ten grains of tannin and two drachms of ether within two hours, with most successful results.

I am happy to say that I had the confidence of the people among whom my labors were spent. I early insisted on cleanliness, both of person and household. I closed many of the cellars and cleared out many of the dark alleys. In most households, I kept a tea-pot full of hot tea constantly on the fire. I had less drunkenness than in many other parts of the city.

Having the confidence of the people, I had them send for me early when attacked with the epidemic, and by thus early treating them I was enabled to prevent the disease from progressing to its usual fatal termination.

In some cases it was difficult to get persons to swallow the ether, but invariably I mixed it with syrup, which made it less unpleasant, and a good large mouthful of flax-seed tea removed the disagreeable taste of the ether. If I needed opium, it was given in ether sweetened with syrup.

With drachm doses of ether mixed with syrup, given every half hour or hour, I treated many cases of diarrhœa —cases that seemed to me choleraic in their symptoms.

IS IRON GIVEN ALONE OF ANY THERAPEUTIC VALUE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read in the column of "Medical Items," in THE RECORD of February 14th, the paragraph headed, "Is Iron given Alone of any Therapeutical Value?"

In my own case natural iron-water was of very great value, after iron in several other forms had failed.

I was troubled with a chronic otorrhœa and many other anæmic symptoms. I tried iron in various forms without other effect than a constant headache.

I had given up the use of iron entirely for several months when I began to use the chalybeate water, intending to give it a thorough test. I used no other water, and drank the chalybeate frequently when I was not thirsty. I used no medicine whatever.

In less than a week the otorrhœa had entirely disappeared. My appetite, which was diminished when using the other forms of iron, began to improve, and at the end of a month I had made a considerable gain in weight.

I continued to use the water two months constantly.

I have passed the winter since in much better health than for eight years, and a small fistula which has been in the habit of healing in the summer and opening in the winter months has failed to put in its appearance this winter.

C. C. FROST, M.D.
NASHVILLE, TENN., February 20, 1885.

THE HABITAT AND TREATMENT OF OXYURIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue for January 31, 1885, is an interesting article by Dr. Millard on "The Habitat and Treatment of Oxyuris." He introduces the article by some criticisms of our standard text-books on the practice of medicine, and the diseases of children, for their faulty statements as to the habitat of this parasite, and states that for correct information it is necessary to consult the specialist in this department. Having had to consult various text-books at my command during the past winter on this subject—having some troublesome cases of oxyuris on my hands—I was struck by this statement, as it was so different from my experience as to what these works said. In defence of the writers on these subjects I here give the result of my readings. Taking one of the older works which I happen to have in my possession, viz.: "Tweedee's Library of Medicine," ed. 1842, vol. iii., page 626, it says: "The rectum seems to be the peculiar seat of the parasite, though it is also found in other parts of the large intestine, and masses of them are often expelled enveloped in mucus or rolled into a ball." On pages 627 and 628 full instructions are given for treatment by enemata, and especially the aiding of the former by purgatives, saying it is generally necessary to keep the upper as well as the lower portion of the alimentary canal clean by the administration of a free purgative, as of calomel and jalap, repeated according to circumstances; also quoting from Horbeden, who says: "Those purgatives are best which act briskly, and of which purging waters are of this kind; and jalap especially for children, two or more grains of which may be repeated daily."

Tweedee further says: "Purgatives which act more particularly on the rectum, as aloes, are extremely useful, and *those which bring away the greatest quantity of mucus*, and thus deprive the worms of their pabulum, afford most relief. Lastly, it must not be forgotten in the treatment of ascarides that in many cases these remedies will necessarily afford only partial and temporary relief, unless at the same time we pay attention to the restoration of the general health and the establishment of a proper degree of tone to the digestive organs."

This is quite full and explicit, although taken from a work long since out of print. Again, Wood, in his "Practice of Medicine," vol. ii., page 688, says: "The peculiar seat of ascarides is the rectum, but they also inhabit the *colon* and are said to have been seen occasionally in the stomach." Of more recent works, Bartholow is very explicit upon this point. In his work on "Practice of Medicine," page 123, he says: "The oxyuris is not confined to the rectum nor its excursion limited to the perineum and vagina. It migrates upward into the large intestine and develops in the cæcum, but the lower part of

the ileum is also invaded. . . . It should not be overlooked that they exist in the cæcum and the lower part of the ileum in large numbers." And he advises treatment accordingly. The administration of one of the vermifuges, especially santonine, aided by calomel, should be the first step in the treatment: as soon as it has acted the bowel should be irrigated by a weak solution of quassia or aloes. Also, Dr. Ransom, in "Reynold's System of Medicine," vol. iii., page 289, says: "It normally inhabits the colon of man only, especially in the neighborhood of the rectum," and quotes various specialists on the subject. In treatment he is not as satisfactory as the others. In special works on diseases of children, I find that "Condie" says, page 242, "It is found in the large intestine, particularly in the rectum of children." Of treatment he says: "In case of children infested with oxyures, the same general treatment will be proper as in other varieties of intestinal worms," and gives full instructions for the use of various anthelmintic injections, but also insists upon a course of treatment calculated to restore the healthy functions of the alimentary canal.

Also, Dr. J. L. Smith, in "Diseases of Children," first edition, p. 401, says, "Its habitat is the large intestine, commonly the rectum," and quotes Brunser as finding it in the cæcum. He advises use of anthelmintics as adjuvants to the main treatment, which should be local. Further, Eustace Smith, in his interesting little work on "The Wasting Diseases of Children," 1871, p. 170, says, "The seat of the worms (oxyures) is the lower part of the colon, especially the *sigmoid flexure*." Treatment: "The oxyures in the rectum and sigmoid flexure are within easy reach of injections and are best treated by this means." The diarrhœa which is so common when oxyures are present is readily arrested by a purgative, as castor-oil or the following powder: ℞. Pulv. jalap, grs. v.; pulv. aloes soc., gr. j.; pulv. scammoniæ, grs. v. M. To be taken every morning for two or three days, and use injections every evening until no trace of the worms is found in the stools or returning enema."

In some cases, I have used locally, after the internal administration of vermifuges, a suppository containing five grains of sulphur and two grains of santonine at bedtime, followed in the morning by an enema of infusion of quassia. This (oxyuris) is one of the lesser ills of the flesh, but a very annoying and distressing one, and as Dr. Millard has shown, one which may last for years, as I can also testify. It is well for us to remember that the local treatment will not always reach the seat of the trouble; still our general writers are not, I think, open to the criticism made by Dr. Millard.

Respectfully, W. H. Sharp, M.D.

Volcano, W. Va., February 10, 1885.

THE NECESSITY OF PURE BOVINE VIRUS.

[We give below the substance of a long communication from Dr. Martin, who deprecates the fact that the production of bovine virus is largely in the hands of irresponsible individuals and companies.—Ed.]

To the Editor of The Medical Record.

Sir: In your issue of February 21st is a communication from Dr. W. H. Doughty, entitled "An Experience with Bovine Virus in the Vaccination of Children," in which he holds up animal vaccine virus to unfavorable comparison with the humanized. Of late years there have appeared a number of communications in the medical press of the United States, narrating bad results and even deaths following the use of animal virus, and many of them advising the abandonment of animal vaccination.

In some of these cases it is plainly evident that the unfortunate complications were due to other causes than the quality of the virus used; but in an abundance of instances it has been clearly shown that the animal vaccine virus of commerce has been directly responsible for the results. I therefore feel called upon to make a few remarks upon this subject, and endeavor to rescue from unmerited reproach a method which I consider an incalculable improvement and blessing. It is extremely doubtful if a particle of the old humanized virus formerly used in this country at present exists, what is now called humanized virus being but a few human removes from the cow, so that it would take some years, were we to try to follow the advice of these writers, to get back to the lamentable condition of things which existed before my father introduced animal vaccination.

The explanation of the cause of the bad results reported is very simple, though, strangely enough, it does not seem to have occurred to the reporters; for, as is extremely unfortunate for the cause of vaccination, they appear inclined to regard everything that is offered in the market under the name of animal vaccine virus as possessing precisely the same virtues, no matter whether it come from a competent producer or an ignorant quack; and never for a moment realizing that they themselves are responsible for a want of proper care in the selection of material used, they throw all the odium upon the method of animal vaccination. . . .

That there should be a number of sources for the supply of animal virus in the United States, conducted by thoroughly competent men, is desirable and indeed necessary, and a few such have been established; but unfortunately a host of utterly incompetent and unscrupulous men, actuated merely by the greed of gain, and with no reputation to sustain, some of them with no medical degree whatever, and others armed with only the diploma of some bogus medical school, have rushed into the field as producers. These men, generally concealing their individuality by the convenient cover of the title, such and such a "vaccine company," underbidding each other in price, advertising extensively, and offering bribes to boards of health, have reduced one of the most solemnly responsible medical specialties to the level of a very low trade. Of course, with the feeling which seems to prevail among the majority of the profession in this country, of utter carelessness as to the source from whence the virus they use is obtained, and of procuring it of the nearest druggist, or of any one who will supply it a few cents cheaper, or at a little more ease to themselves, such propagators will supply a large proportion of the virus used, and reports of bad results will increase and multiply. Those who meet with them, however, have no right to attribute them to the practice, but rather to the malpractice of animal vaccination. I would here protest most emphatically, that the method of animal vaccination introduced by my late father, and practised by him, and myself, and other competent men, has nothing to do with, and is in nowise responsible, for the practice of it which largely obtains in this country. . . . Stephen C. Martin, M.D.

CHOLERA AND ITS RELATIONS TO STATE MEDICINE.[1]

BY S. OAKLEY VANDER POEL, M.D., LL.D.,

PROFESSOR OF PUBLIC HYGIENE, MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

CHOLERA interests from two aspects of study: First, to the physician, in which its symptoms, pathology, and treatment call for his patient investigation; where each case is regarded in its individuality, and where his recorded observations of the particular case forms the specific type of thousands which he subsequently meets; in the study of which he strives to formulate methods of palliation or treatment which may mitigate, if they cannot cure, the disease. Naturally this forms the first element of study upon the appearance of a new disease, and it was in this restricted field that all the earlier literature of cholera abounds. There are those before me who will readily recall this period in the study of the disease; for sixty years have not yet passed since cholera was an unrecognized and unknown disease, both in Europe or this country.

When, however, we study cholera in its *epidemic* relations, a larger and more extensive field is presented. We regard no more its action upon the individual, but as a devastating scourge which attacks whole localities and nationalities. Larger and more extended studies are then necessary. It is no more the study of the individual case in its personal aspects, but its relations to others; relations in which the individual work of the physician is but a component part of the work falling upon every individual, but which, for its harmonious and effective working, must devolve upon constituted authorities, and falls, therefore, in the domain of study now known as "State Medicine."

Indeed, in medicine there are few studies as laborious as the study of *epidemics*. Necessitating, as an essential point of departure, a knowledge of the disease in its clinical and anatomical characters, it imposes, in point of view of the etiology and prophylaxis, a series of investigations different from ordinary pathological researches, or mere knowledge of therapeutics.

It is no more the study of the disease itself, in which ordinary medical observation may more or less circumscribe the affection so far as determining its etiological relation with the persons and things surrounding, and thus arrive at a curative formula, based upon the examination of the single disease. But it has to do with a disease which strikes at a more or less considerable mass of individuals—possibly an entire population—disease, the universality of which will not permit the isolation of each case, to investigate the limits of its organism in its relations with others.

From a condition relatively simple in sporadic affections, is substituted a complex mass of similar cases. He recognizes a higher duty than the mere care of the individual case—the sentiment of the necessity of a common *preventive* treatment—the institution of prophylactic measures, the benefit of which may extend to a locality or to a State.

If, further, we reflect upon the obscurity which, even now, still weighs upon the conditions of the development of epidemics; if we recognize that upon the globe there is not a country which does not present different conditions of predisposition, or of immunity with reference to these scourges; if we consider that the prevention of epidemics depends not only upon the nature of the disease to be contravened, but also on a host of different circumstances, such as conditions of climate, of locality of the place to be protected; or, again, whether the topographical conditions of a country render efficient quarantine applicable; or, again, the receptivity of the people, whether from race or previous sanitary state; or still more, by density of population and the frequency of its commercial relations, you will appreciate how numerous the difficulties are to be overcome in the study of epidemic disease.

Although the studies of the past twenty years have greatly modified the *supernatural* as the intimate cause of epidemics, and while sanitary researches have pointed out the numerous accessories which facilitate their rapid and wide-spread diffusion, very much still remains which is intangible and hypothetical. Those who have made themselves familiar with the history and literature of grand epidemics well appreciate that much in their outbreak and spread still remains mysterious and obscure. While I recognize to the fullest extent the influence of telluric causes, the hygienic condition of localities, the sanitary condition of a people for the resistance of disease, neither one nor all combined can explain those fearful outbursts of a disease, which had been characterized by no especial virulence, productive of no great mortality, when it suddenly assumed the features of a devastating scourge and spread with rapidity over the civilized world.

A wide range of study must then be begun. It is no longer the personal features of an individual case, but the study of everything which pertains to the natural history of the disease. Its place of endemicity, its modes of propagation, its period of incubation, circumstances which may favor or retard its spread, and finally the most effective measures to be adopted for its contravention, become, each in turn, so many points of practical interest.

Nor have governments, particularly those of Europe, been indifferent in this respect. Hardly had the wail which followed the track of the first incursion of cholera in Europe, in 1831–32, subsided, when the necessity for some concerted action was spontaneously felt. An International Sanitary Conference was assembled to discuss and devise means for its contravention.

Even then, when the ideas of the modes of its propagation were of the most contradictory character—the one ascribing it to an "epidemic influence" against which human agency could effect but little; a visitation of Divine wrath against which we should not contend, but recognize as worthy punishment; or, secondly, as owing to some obscure meteoric influences, whereby was wafted, by atmospheric currents, the subtle and intangible poison to unknown distances; or, thirdly, the positive influence of contagion or infection, even then, through all this mist of contradictory opinions, the practical fact was not long in establishing itself, that whatever might be the infectious principle, in no instance had it travelled or been transported faster than man himself travelled. This was a great point to establish, for it gave a basis upon which to work for its contravention.

[1] Read before the Society of Medical Jurisprudence and State Medicine, April 9, 1885.

In the light of present knowledge, those first efforts seem feeble and very imperfect, but they were steps in the right direction. In the peculiar section of country, and modes of travel in which they were tried, they accomplished much; but the rapid strides of commerce, the more active interchange of persons and merchandise, brought new factors to the problem, which have called for long and patient work; but the requirements have, I think, been met. Were they fully carried out, cholera would have but an historical interest to the inhabitants of Europe and the Western Hemisphere.

But what is cholera? Where is its place of endemicity? What are the factors of its transmission, and what the measures to contravene its progress? To the first question, it is not necessary in this connection to reply, merely contenting ourselves with the assertion that it is neither malaria, nor miasm, but probably a specific germ, the origin of which has not been established. All my hearers are conversant with the extended studies which have of late been made by pathologists in Europe, tending to establish this opinion. Though the circle of evidence may not be absolute to verify the claim, still all analogy favors the opinion, and all efforts for contravention rest upon this basis of belief.

It is different, however, with regard to its place of origin. By universal assent India is the native habitat, and an epidemic which is recognized as the most pandemic of all known scourges, has its origin in a comparatively limited section of country; this is at the delta of the Ganges, comprising an area of about three hundred square miles. In this locality the disease has existed for centuries, with repeated epidemics which have spread over Hindostan, but which never reached the confines of Europe until 1831–32. Other places have since become secondarily affected, and it has become in them a permanent disease; at times comparatively latent, and then breaking out with renewed violence. Notable among these secondary places of infection is Bombay, the great seaport on the west coast, from which the principal commerce of the Western world starts. The statement of this fact explains the sensitiveness which has always been manifested by the British Government and by her agents in all the international conferences which had reference to the contravention of cholera. India, now regarded as an integral part of the British Empire, has enormous commercial relations with the home government. The obstruction of these relations, even in a remote degree, excites a feeling in the commercial circles of England which is at once reflected in the action of the government.

The agents which keep alive, and even intensify the virulence of the cholera germ, are the numerous and grand pilgrimages called for by the religious belief of the people. Even in Hindostan, independent of the Mohammedan pilgrimages, there are those of other beliefs, which call forth aggregations of nearly a million of persons. It is markedly the feature of cholera, that whenever aggregations of any kind occur, with their attendant filth, poor food, and fatigue, the disease assumes virulence and intensity. Particularly so when conditions of the *soil*, one of the most powerful factors, both for retention of the germ and intensifying its action, are present. A notable instance of the effect of aggregation has been noticed in vessels carrying passengers by the Red Sea route. Cholera, as we have stated, is now ever-present in Bombay. So long as vessels carrying passengers from there take only cabin passengers, cholera has not appeared upon the vessel, but whenever pilgrims are taken in the steerage, it is almost sure to develop.

The pilgrimages which take place in India proper, great as they are, would not of themselves spread cholera over the civilized world. There is also a large Mohammedan population. It is one of the fundamental tenets of that creed that every true believer must once in his life make a pilgrimage to the sacred shrine of Mecca, in Arabia. These pilgrimages must be so timed that from every portion of the Mohammedan world they reach the shrine at about the same time, the period being between the latter part of December and about the first of February. Formerly this was done by caravans, taking months to accomplish the journey. Thousands perished by the way from sickness and fatigue, but the swarming legions, fanaticized, ever pressed slowly on. Death under such circumstances was but to propitiate in a greater degree the favor of the prophet. Oftentimes over two hundred thousand were gathered at the sacred shrine. Caravans from India, Persia, Arabia, Syria, and Turkey, from Egypt, and the whole of Northern Africa, met in one indiscriminate mass. On their return they carried with them the dreaded scourge, leaving the germs on every part of their extended route. This explains the slow and peculiar course of the first two epidemics, which reached Europe by way of Russia. The epidemic which reached Europe in 1831 left India in 1815, and was seventeen years in making the transit. It passed through Arabia, along the shores of the sparsely settled Caspian Sea, and so on to Russia. When, however, it reached the denser populations of Europe, its spread was rapid and almost instantaneous. The measures which were at first formulated by the International Medical Conferences had in view only this route of introduction. When, however, in 1865, cholera suddenly appeared in the Red Sea, Egypt, and along the European shores of the Mediterranean, it was evident that new influences were at work, and that an entirely new study of the problem must be made. Up to that time, measures for contravention had been taken with a view to its incursion by way of the Caspian Sea. These had consisted chiefly in stationing small bodies of troops on the great caravan routes, in the most sparsely settled districts, with a medical officer at each to examine and isolate all cases of the disease. Originally five such stations had been created, but from time to time the number had been increased, until there were fifteen, circumscribing perfectly the land route. So long as cholera reached Europe only by the land route this measure was successful. It was so only from the exceptional character of the country—very sparsely settled, and impossible of transit except by the caravan route—that isolation could be maintained. I allude to this feature to deprecate the principle of *land quarantine*. All experience has shown its utter inutility, and as causing needless, and many times disastrous, obstructions to passage of persons and merchandise. Reference need but be made to the futile efforts during the past summer of the Spanish and Italian Governments. But the days of caravans composed of pilgrims to Mecca are ended. But one now goes yearly, that starting from Cairo, by way of the Isthmus of Suez. Steamships have taken their place, and a new class of factors had to be considered to meet the emergency. While the spread of the disease by this new method of transit was much more rapid and sudden over the civilized world, there were other conditions which rendered contravention of the disease even more feasible than when attempted upon caravans.

First, the pilgrims were saved the long, exhausting journey of the caravan; their hygienic condition could be more certainly watched; they arrived in a far better physical condition; their aggregation was for a comparatively short period, while their food was more healthy and more regularly dispensed. In order that you may form some idea of the magnitude of the undertaking to transport this vast mass of humanity, it is sufficient to state that from sixty to a hundred steamers are occupied in the work; that they represent nearly every nationality of Europe, though England furnishes the majority. Not only must these steamers bring them to Dejeddah, the seaport of Mecca, but they must await their return after an absence of a month in most instances, re-embark them, and distribute them to their homes over the vast territory of the Mohammedan world. They illy brook the delay of frequent inspections and re-embarkations, and

however willingly the truth of the principles of the International Sanitary Conference may be received, every method of obstruction is resorted to to evade their literal adaptation. Added to this, as the whole work of observation of necessity takes place on Turkish territory, the executive work is largely done by Turkish officials. It requires but to mention the fact to realize that much of it is synonymous with inefficiency, to use no harsher phrase. England, whose commercial interests in this great highway are so great, illy brooks the repressive measures; her influence in Turkish affairs is recognized, and her government has many times, through her agents, thwarted the rules laid down by the Conference. Not only through the action of the government, but her medical literature has teemed with articles tending to discredit all repressive measures. Writers, both in India and England, insist that cholera is not contagious, while still another class are equally strenuous that an "epidemic influence" is the pervading cause. We can only allude to this strong feature in the literature of English writers on cholera to caution readers against the too ready acceptance of such doctrines. They are inspired, it may be unintentionally, from the desire to place as few obstructions as possible to the supremacy of her commerce, placing reliance for immunity on the thoroughness of local hygienic measures rather than contravention to commerce.

France, however, by her geographical position and her climatic conditions must, as in this country, protect herself constantly against the invasion of two epidemics: that of yellow fever on her Atlantic seaboard, and of cholera and plague in her Mediterranean ports. Of all countries in Europe her sanitarians have best formulated the necessary provisions against the invasion of these epidemics, and show the best results of their protective influence. At the risk of seeming irksome and tedious, I shall narrate some of the principal of these provisions, as formulated by the International Sanitary Council, largely under the inspiration of the French physicians. It is the more necessary, because in studying them you study the underlying principles upon which all rational quarantine regulations must rest. Understanding them, you can make their application to any country and any clime.

The problem was large, and required large conceptions and broad ideas to grapple it successfully. Have you ever given thought to the immense body of human beings who gather annually at Mecca. Accounts vary, but estimates rarely place the number under one hundred and fifty thousand. Then, too, think of the character and habits of this mass of humanity. Without the slightest notion of sanitary precaution, huddled and crowded in the filthiest conditions, with insufficient and irregular supplies of food, in a climate and season when prolonged rains and cold are followed by a tropical sun and festering miasma; drinking from polluted wells, exhausted by prolonged travel, lying in the open air, or under the slightest tents—all conditions which, taken even separately, would favor the explosion of epidemic influences. Very many of these conditions, under proper supervision, have disappeared, while under the more speedy modes of travel they reach Mecca less exhausted, and remain in the vicinity a shorter time.

The whole stay in Arabia is not now over four weeks, enabling the sanitary supervision to be more concentrated. The sanitary contraventions now employed are not the evolution of a single sitting of the International Sanitary Commission, but developed from year to year as necessity and experience may have shown to be advisable. Some, which would seem the most important, and would be suggested as among the earliest restrictions, have only been put in force within the past two years. Manifestly, as the disease came from India, it would be thought of prime necessity that the pilgrims from that country should be examined before landing or approaching the shores of Arabia; yet this is one of the latest measures put in force. For if the disease existed among the pilgrims, they should not be allowed to mingle among the great mass coming from every other quarter of the Mohammedan world. Fortunately exceptional facilities are at hand for this purpose. At the entrance of the Red Sea is the island Camaran, some fifteen or twenty miles in length, by three or four in breadth. Its surface is undulating, somewhat wooded, and well supplied with water. At the lower part of this island vessels containing pilgrims coming from India are compelled to stop, and disembark their passengers for inspection. If all are well, they re-embark and proceed to Dejeddah. If, however, cholera is discovered, they are sent to another station, a few miles further up on the island, and are there detained until ten days elapse after the appearance of the last case.

It is not necessary to refer here to the measures of cleansing, isolation, and disinfection practised, as they are the same as pursued in every well-appointed quarantine. When the term of detention has expired, they re-embark and proceed on their route. It is apparent that if these measures are faithfully carried out, cholera should not appear in Arabia. Now it is this very obstruction against which England particularly protests. The delay occasioned is obnoxious to her commerce, and yet to the unprejudiced observer it is a measure so vital to the welfare of Europe and the world that it should not for a moment be considered.

Arrived at Dejeddah they are reinspected, and if no sickness is found they form in caravans and proceed at once to Mecca. With the caravan are placed the Medical Inspectors, who watch carefully the sanitary conditions, and promptly isolate a suspicious case. Sanitary regulations are enforced as much as possible among so miscellaneous a gathering. At each halt pits are dug for the dejections and covered up. All camp refuse and dead animals are buried. Drinking-water is kept as much as possible from pollution.

On the return of the pilgrims to Dejeddah, all, irrespective of nationality, are subjected to a quarantine of observation. If after five days there is no appearance of cholera they are allowed to embark on vessels for their respective destinations. Those who are to pass through the canal must undergo another inspection at Thor, some sixty miles before reaching it. Pilgrims from countries other than Egypt pass through the canal in quarantine; that is, they are not allowed to land or hold communication at any point, but the vessel must proceed direct to its destination. With the honest and full enforcement of these conditions cholera should not be a European scourge. The use of steam in the transport of pilgrims, while hastening the spread of a neglected epidemic, at the same time allows the application of restrictive measures with much more certainty, because the pilgrims are kept in fixed routes, and all must come under the same regulations.

You will notice the underlying principle in all these methods of contravention is based upon the *period of incubation* of the disease. It is no blind obstruction, founded on fear or caprice, but wholly on the natural history of the disease, its period of incubation, its modes of transmission, whether from the individual or his surroundings. We know cholera to be one of the most contagious of all diseases in the persistency of the vitality of the poison, its rapid dissemination, and the numerous ways by which it can be transmitted.

Perhaps it is well to mention here how cholera is transmitted from person to person, or from locality to locality. In the recital made, it is evident that atmospheric influence has a very inferior agency in its transmission—at no time has the contagious element travelled faster than man himself. The first outbreak of 1831, coming by the slow caravans along the sparsely settled district of the Caspian Sea, required eighteen years to reach Eastern Europe from India. Later epidemics have followed the means of communication between countries,

the steamships. To whatever portion of the world it subsequently spreads, it does so by the means of communication employed by man in any particular district. The contagious element is, then, primarily in the individual himself. This element is in the human dejections. We do not stop here to discuss the particular element which propagates—that belongs rather to the field of pathology, and has received within a recent period, through the researches of Koch, of Berlin, almost a mathematical demonstration. Secondarily, whatever these discharges touch becomes contaminated, and may become the focus for a new spread of infection—the hands of attendants which become accidentally soiled, bed-linen or clothing, or again the soil itself, under certain conditions which have not been wholly defined, becomes one of the most tenacious foci of infection. I do not refer to the soil in this connection as an element of filth as disease propagator, but in every epidemic, irrespective of local sanitary conditions, there have been certain districts, apparently refractory to the epidemic influence; even though the disease reached there it soon died out, without special sanitary precautions. So marked has been the tenacity of the poison to remain in certain soils, that Pettenkofer, of Munich, has presented a vast array of facts tending to prove that the poison emanates from the soil itself. When this does occur, it is a secondary, not a primary factor.

While these conclusions are accepted by the great mass of medical men, there is still an influential body, chiefly in England, who deny wholly all contagious influence, and insist that the spread of the disease depends upon "epidemic influence." It is not necessary to stop and seriously controvert these assertions, nor the facts by which they are upheld. There is, however, one point which has always been a stumbling-block to the believers in specific contagion, and which, so far, they have failed to explain; but which, taken in the light of recent germ studies, becomes an argument in favor of, rather than against, the specific transmission of the disease. When plague formerly ravaged certain sections of Europe, it was frequently observed that in districts where the disease had not as yet shown itself, non-febrile buboes became very common, and preceded for some time the incursion of the disease. So too with cholera. Prior to its epidemic and virulent appearance, there is a period, variable from weeks to months in some cases, where diarrheal diseases are far more common than ordinary, though no special fatality attends their presence. These two circumstances are largely dwelt upon by those who believe solely in epidemic influence. In this country the list of epidemic diseases could easily be extended to yellow fever. In every incursion of that fearful malady there has been what might be termed an "incubative epidemic period." The disease has not started off in full virulence, but has required a certain time to reproduce itself, or rather for successive reproduction of germs, the activity depending in a great degree upon the elements of filth, heat, and moisture to favor the propagation. So, too, in plague and cholera. When the non-febrile bubo is present, the germ has already gained a foothold. In cholera, where what is termed cholerine is present, there is already the specific germ, feeble it may be at first, but which by successive reproductions and favorable adjuvants gains in intensity, in deadliness, and rapid dissemination. Even without the demonstration of specific germs, which has been so incontrovertibly done, the above explanation would seem to be suggested by so many natural results emanating from feeble causes, as to present themselves almost unconsciously to the mind. This point disposed of, it seems to me the advocates of pure epidemic influence have no more a tangible argument upon which to rest. Cholera is a specific disease. All analogy points to a specific germ. Science has demonstrated its actual existence. . . . Passing then from this recital of the workings of quarantine, with reference to the Mohammedan pilgrims to Mecca on the shores of the Red Sea, let me for a few moments call your attention to the position of this country with reference to the contravention of the scourge. But first let me point out the distinction with reference to the word "quarantine," as originally used, and its signification as applied to-day. The word is an unfortunate one to be applied to measures of sanitary observation. Originally it had reference to the forty days' restriction which the countries bordering on the Mediterranean Sea, more particularly Italy, enforced against the progress of the plague. It has no such meaning to-day; but comprises the whole series of measures, restrictive as well as hygienic, employed to contravene the incursions of an epidemic. These are not limited to those taken at the port of arrival of a vessel, but include those which, in my judgment, are far more important, the *inspection of passengers and luggage before embarkation*, their systematic inspection in transit, and finally, their observation and inspection on arrival at port. As I mentioned, the inspection on embarkation must not be confined to the passengers alone, but what is more important, must include their *effects*.

Cholera, as we have stated, is transmitted solely by the dejections of the individual. Whatever these dejections touch or stain will transmit the disease for an almost indefinite period. Any piece of soiled clothing may be the nidus to cause an outbreak of cholera thousands of miles distant. In this connection it may be well to mention that the action of the Holland Government, during the past summer, was the most rational, as well as the most effective, of any taken by the other European powers. While they had upon their frontiers cordons of military to obstruct the passage of persons and articles of commerce, or again in other places subjected passengers and baggage to needless and even dangerous fumigations, the Government of Holland, on arriving at her frontiers, not merely determined that all travellers were well, but also made a thorough inspection of every article of clothing. If there was a soiled piece it was taken, the name and residence of the person from whom it was taken given, and in two days the article was forwarded to the owner in a clean condition. Very little delay, and no obstruction was thus made either to passengers or their surroundings.

I would therefore earnestly urge that said inspection of passengers and baggage be at *once* commenced by the agents of the General Government at all ports of Europe, from which emigrants embark for this country. To delay such action until cholera reaches our shores would render the whole system nugatory. If the luggage contains no germs of the disease it is perfectly simple to manage the individual. The time of transit is longer than the incubative period of the disease.

If, therefore, the person embarks with the disease undeveloped in his system, it will certainly show itself on the passage. Now a vessel, strange as it may seem, is one of the best places to jugulate cholera. If the inspection of the passengers is made at sufficiently frequent intervals, a case can at once be detected and isolated. When so isolated, place the attendants in absolute quarantine. Have the discharges passed in a vessel containing a solution of one part in a thousand of bichloride of mercury. They are at once rendered inert, and should be thrown overboard, precaution being taken that they do not touch the sides of the vessel; for should any portion of the discharge escape disinfection, and lodge on the side of the ship, it would become a new nidus for propagating the disease. Should any piece of bedding become stained, either destroy it at once or throw it into a solution of sulphate or chloride of zinc, and if by accident the hand of the attendant is soiled, wash it at once in a similar solution

Cholera can in this way be stamped out before the vessel reaches our shores, because as the time of transit exceeds the period of incubation every case which occurs must have brought the germs in his system when coming on board. If the measures above stated are faithfully carried out, the contagious element is rendered inert. We have therefore little to fear from its spread to

other passengers. Nothing, then, would remain for the quarantine authorities at our ports to regulate, but keep the vessel and passengers isolated and under observation a sufficient length of time from the last case, to be certain that no new cases occur.

It is evident that if preventive measures are to be effectual, they should be instituted at *once*. In a short time we shall have the flood-tide of emigration coming from every portion of Europe. Although thus far during the present epidemic in Europe none of the seaports from which emigrants depart have been invaded by the disease, we must bear in mind that these emigrants congregate from every locality, bringing with them, it may be, soiled and infected clothing, which I deem far more dangerous than any contagion from their persons. It is at these ports that the examination should be made. If we wait until the disease reaches our shores, such preliminary inspection would be almost useless, and the Government would be judged derelict in its failure to perform a duty which every sanitarian would deem of the first importance.

The time has come when neither the General Government nor municipalities can wait supinely the advent of a scourge.

It is no more the judgment of an offended Deity, under which one must supinely sit, but an active, deadly entity, which can be contravened, and which calls for the active intelligent efforts of those having this matter in charge on the part of the State and national authorities.

Of course, from what I have said the natural inference is that cholera will certainly be a visitant of this country the coming summer. Such, however, is not necessarily the case. The epidemic of the past season in Europe showed no inclination to travel to the northern seaports. During its reign at Paris, although intercourse with England and other countries was practically unrestricted, no case occurred, so far as I am aware, north of Paris. During the winter it has been quiescent, and it is to be hoped that the prompt sanitary precautions taken at the time have jugulated the disease.

While I deprecate the efforts which have been made in certain quarters to induce a panicky feeling, I should encourage unusual activity in all measures tending to place the city in a good sanitary condition. Bad as the surroundings of many of the tenement-house population are, they are, on the whole, much better than many of the same class in London, Paris, and Naples. While widened streets have lighted up many of the bad places in those cities, it has, on the other hand, not driven the inhabitants to larger quarters, but has crowded them more densely in the same districts in which they resided before. The problem is much larger than the mere superficial sanitarian would have us infer. Economic questions, not so vital it is true with us as with European countries, enter as factors. The people are there, they live near their places of employment. The radical reform is not so much in tearing down and building up, as to bring the best possible hygienic conditions to their present position. Give them good sewerage, plenty of water carried to every floor, separate water-closets thoroughly ventilated to every family, encourage by these means habits of cleanliness, and you go a great way to remove the evils which seem inseparable from their present condition. These are changes which can be effected without great expense, and consequently adding to the burden of rents. This, however, is too large a subject to introduce as part of a paper on cholera, and the suggestions are thrown out as hints to encourage the work of public-spirited citizens in the right direction.

A Small Spleen.—Before a recent meeting of the Clinical Society of Maryland, Dr. C. W. Mitchell exhibited a spleen which weighed only one drachm. The individual from whom it was extracted had been a large, robust man.

A READY METHOD FOR THE PRODUCTION OF LOCAL EXTENSION IN THE TREATMENT OF FRACTURES.[1]

By CHARLES F. STILLMAN, M.D.,

CLINICAL PROFESSOR OF ORTHOPÆDIC SURGERY IN THE WOMAN'S MEDICAL COLLEGE, NEW YORK.

Local extension of a limb is indicated in cases of simple fracture, where shortening is likely to ensue, and also in fractures which are compound or comminuted, and the method for its production, to be detailed in this paper, will be found possessed of so much simplicity and applicability as to commend itself to surgeons without very strong advocacy on the part of the writer. In local extension only the parts about the seat of fracture are stretched, while in extension, as usually practised by means of a weight and pulley, or the long extension splint, the stretching is not limited to the affected part of the limb alone, but involves the entire limb.

Fig. 1.

It would seem, theoretically, if thorough extension of the part could be produced by means of traction force directed so as to produce stretching of the injured part alone, that the fracture would be placed in the best condition for prompt repair with a minimum of deformity; and in reality this is true, because, when properly adjusted, such a dressing not only insures better fixation of the fractured bones during the period of repair, but at the same time the traction can be regulated day by day, without the necessity of removal of the splints from the limb; and in compound or comminuted fractures the parts can be dressed and local treatment pursued without disturbance of the fragments or removal of the splint.

As an illustration of this method for the production of local extension, we will suppose an instance in which the fracture has taken place in the forearm, midway between the wrist and elbow. The requisites are: First, two stout wooden splints, notched at each end, as in Fig. 1; second, some strong moleskin plaster (the double-twilled, prepared for extension of joints, is best); and third, some strong webbing strips.

Fig. 2.

First cut *four* strips of the moleskin plaster of sufficient length to encircle the arm, and from two to three inches in width.

These should be cut in the fan shape, shown in Fig. 2, and have strips of the webbing sewed to them, as shown in the same figure.

To the end of *two* of these strips buckles should be attached.

To apply the splint the four adhesive strips should be placed upon the forearm, two above and two below the seat of fracture, and on opposite sides of the arm, the extremities interlacing, as shown in Fig. 3, care being taken to avoid covering the seat of fracture. The wooden splints are now to be placed, one on either side of the arm, and held there in position by circular strips of adhesive plaster in the usual manner.

The next step consists in drawing the webbing strips

[1] Dr. John Swinburne, of Albany, read a paper before the Medical Society of the State of New York, in 1861, advocating extension in the treatment of fractures of the long bones, but his method for its production differs materially from that here described.

through the notches at the end of the splints. on each side of the arm, and buckling them together, as in Fig. 4.

It will readily be seen that the tighter these linear straps are drawn together and secured by the buckles, the more stretch will be produced upon the parts over the seat of the fracture.

If the fracture is near a joint the splints must be carried beyond that joint sufficiently to immobilize it, but if in the middle of a shaft,

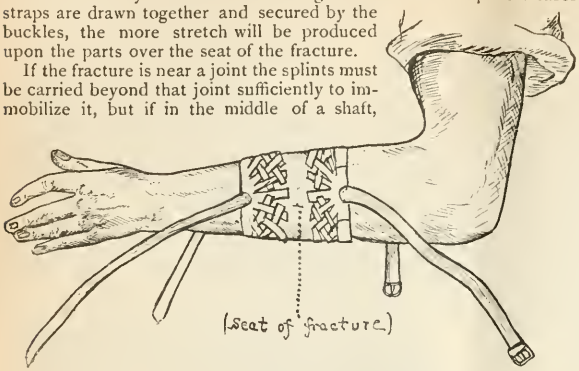

Fig. 3.

fixation of the joint is not a necessity if the local stretching is thoroughly effected.

It may be also suggested whether rubber webbing could not advantageously be substituted for the non-distensible form advocated by the writer.

It would seem, however, that its continuous action would be more apt to produce non-union of the fragments, and at the same time it would certainly cause the adhesive plasters to cut more deeply into the tissues, than if the extension was produced by the rigid webbing.

For fracture of the thigh, *four* short splints are

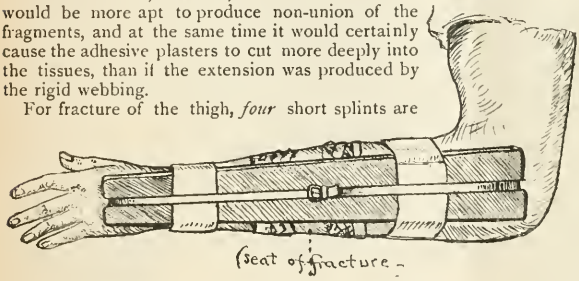

Fig. 4.

used about the length of the thigh itself, and notched in the same manner as those used for the forearm. These will require *eight* fan-shaped moleskin strips, to each of which a webbing strip should be attached, as already depicted.

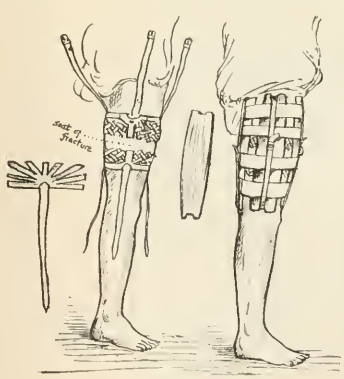

Fig. 5.

These should be interlaced above and below the fracture, and the webbing strips drawn tightly over the ends of the wooden splints, which are to be placed on the four sides of the thigh.

Traction can now be secured as in the forearm, and is maintained and regulated at the will of the surgeon. In most cases it will be found preferable to extend the posterior splint above the hip and below the knee, and secure immobilization of these joints for the first few weeks, but the lateral and anterior splints are not changed.

This method of treatment allows the surgeon to secure a more perfect coaptation of the fragments, and to maintain and adjust the extension; since the latter depends entirely upon the degree of traction which is exerted. The adhesive dressings, when interlaced in the manner just detailed, not only do not slip, but any increase in the traction causes them to embrace the limb more firmly, and, when the strips of webbing are drawn over the ends of the wooden splints and buckled together, such traction as is exerted is held securely, provided the splint itself be of sufficient thickness not to bend under the linear strain.

It is a difficult matter to disarrange the fragments if they have been properly adjusted and secured by the method just described, as the traction causes the parts over the seat of fracture to become stretched, consequently causing perfect fixation of the part by forcing the tissues themselves to act as a local and secondary splint, in addition to the remainder of the apparatus.

Florence House, 109 East Eighteenth Street.

DETERIORATION OF VISION IN SCHOOL-CHILDREN.[1]

By S. O. RICHEY, M.D.,

Washington, D. C.

Wherever "two or three are gathered together" a legitimate field is created for investigation by those interested in the moral and physical welfare of their race; because one may be in health and another diseased, the former, in time, being "made black by handling pitch."

If the hygienic arrangements of private houses, barracks, ships, and hospitals are studied, so should be those of theatres, churches, and schools.

Schools are, to a great degree, protected from the more pronounced contagious diseases, but are they guarded so well as they might be from those that are obscure and less easily detected? Should not each school be insured all possible safety by a preliminary physical examination in every respect of each child entering it? A certificate of vaccination is demanded of each new-comer in many schools; when any of the eruptive fevers are known to exist in a household, no child from that house is allowed to attend until all danger of contagion is believed to be past; but how many there are, especially among the poorer classes, who have some conjunctival affection, and yet attend the schools, associate intimately with those who have not, use the same wash-basin and towel, the same books and pencils? The extent of exposure is not justifiable, and a certificate of health is as important in this particular as in any other.

Reich[2] had an experience due probably to exceptional circumstances, but among three hundred and seventy school-children in Armenia, he found trachoma to exist to the extent of thirty per cent. of the males and twenty per cent. of the females; and there was conjunctival trouble of some character in sixty per cent. of the males and seventy-three per cent. of the females.

Weber suggests that a special physician be appointed with executive authority. This would meet the difficulty

[1] Read October 15, 1884, before the American Health Association, at its Twelfth Annual Meeting at St. Louis.

[2] C. f. A., October, 1878, p. 228.

at the outset, but it would add to safety to banish wash-basins and towels from the school-room, unless each pupil could have his own towel. This last recommendation will not seem uncalled for by those who have seen instances in which the different members of the same family have suffered in a like manner, the source being a single individual and the medium of communication the articles in common use.

A low form of granular conjunctivitis, with its train of consequences—trachoma, distortion of the lids, and pannus—is much to be feared. I have never seen it happen in a very young child but once; it is not infrequent after eight years of age. Landesberg[1] states that he has "seldom seen children under five years suffering with granular conjunctivitis."

An affection of the eye due to contagion is an accident not attributable to the *work* of the school-room; but there is another form of trouble which cannot justly be characterized as accidental, because of the constancy with which it prevails among all schools—a shifting or varying in the power of refraction of the eyes; the refraction *increasing* as the eyes are kept at close work for a long time. This condition of near-sight will in time be as much a curse to civilized people as tuberculosis, uniting as it does the influences of inheritance and acquisition.

Germany, to-day, probably heads the list in the percentage of myopia to its population, especially among its educated people; that country has also been among the first to appreciate the greatness of the evil, in that it disqualifies in a great measure those who have myopia for military duty, and, therefore, for good and efficient citizenship. We, in our neglect, or in the inadequacy of the measures adopted, are rivalling her in our results.

Hygiene will be the medicine of the future, and Prophylaxis the patron saint of physician and layman alike. More is to be gained for our race by avoiding *now*, when it is possible, the sins which will be sure to curse our children, than by all the measures of relief they can reach.

The sage contemplates the probabilities of the future and endeavors to prepare for them; the fool lives in the present, with a selfish regard for himself alone.

He drinks his wine to excess, regardless that his offspring must pay to Nature *his* debts in pain, blindness, general infirmity, and shortened life.

A debauch *is* such, whatever form it may take. No one disputes that excessive guzzling is dissipation; oversleep, over-exercise, anything which exceeds the limits nature has fixed, and which does not give to employment the variety that charms and rests is debilitating, and, in so far, adds a burden to those who come after us.

The overtaxing of any organ makes it *tired*—a street synonym for drunk. Our moralists inveigh against intoxication by drugs, and yet often encourage that of exhaustion, probably not realizing one to be as bad in its effects as the other. How often does one see this individual at his work giving testimony against excesses, while he himself exhibits the pallor and exhaustion of late hours, hard work, and mental anxiety, the result of which is felt by the child born of his wearied body! He forgets this possibility, and that the book from which often he gets his inspiration says, "The sins of the fathers shall be visited upon the children, even unto the third and fourth generations."

Others, with this example, are inclined to act in the same manner. The children of these individuals begin the work of life handicapped, and their school life at a very early age.

They must contend with the offspring of more vigorous parents, and, to keep abreast, must make greater effort. The working organs are forced to labor beyond that which allows of health, and structure change follows. The bow is never unbent, and it breaks. With longer persistence come greater changes and increased disqualification, which in turn are handed down to their own children, who then have the burdens transmitted by the father and the grandfather.

As living means struggling, there is rarely an opportunity to retrace our footsteps; therefore we must go *on*, and moving on struggle at a greater disadvantage with each succeeding generation, so the end of such a family can easily be predicted, because the evil influence calculates by geometrical progression. What is said of a family is true also of a race, except that the causes are in greater variety and intensity, and require a longer time, though the ultimate conclusion must be the same.

Let the organ of the body which shows this tendency to depreciation be what it may, the best method of procedure is that of prevention. The ills which our bodies suffer were probably not existent at first, but are the outcome of a long series of indulgences by our fathers. We should hold *them* responsible for them, and *ourselves* accountable for any addition to them which may be manifested in our children.

We should not be profligate in study more than in other things. It is selfish to ourselves to enjoy our patrimony, to spend it all, and then to propagate children who will inherit from us nothing but ills.

Though myopia may not exist in a given instance, the tendency may be inherited, and if any ancestor has had near-vision, the precautions against it should be increased. We have here to discuss school work as a probable cause in the production and increase of myopia and the best means to prevent or lessen it, if possible.

A small proportion of very young children in this country have a high degree of myopia, which is inherited, and these must be excluded from the discussion.

It is not infrequent that the individual begins as a hyperope, the refraction increasing to emmetropia (or normal refraction), to myopia, and progressive myopia.

The statistics, which are large enough for conclusions, show in our own and in foreign schools a gradual increase in the percentage of myopia from the lowest to the highest classes. The persistent use of the eyes at short range upon objects improperly illuminated, or for other reasons insufficiently distinct, is believed to be the prominent factor in its production.

Dobrolowsky, in examining the children of the Ural high school, finds myopia infrequent—12 per cent. of the whole. These children live much out-of-doors, and their high animal spirits, no doubt, so much diminishes their taste for mental work that they do less of it than many others. Compare the above with what follows.

Durr reports that among the scholars of the Lyceum, Hanover, in the lowest class there is 15 per cent. near-sight and 94 in the highest, with a mean of 37.7 per cent. In the lowest class there was 81 per cent. of hyperopia, allowing only 4 per cent. for normal refraction.

Reich found in a girls' school 12 per cent. myopia in the lowest class, and 53 per cent. in the highest, with an average of 33 per cent.

Dunnert examined 1,133 pupils of Hyde Park schools: 76 per cent. were normal; 12 per cent. of the rest were hyperopic; 8 per cent. were myopic, and 4 per cent. miscellaneous. Only 18 per cent. *under* ten years had eye trouble; among those over fifteen years emmetropia was exceptional; myopia increased from 3 *per cent. between five and ten years to* 30 *per cent. between fifteen and twenty years*—ten times.

Zehender[1] in his examinations found nearly 11 per cent. myopic in the sixth or youngest class; in the fifth class, 16; fourth, 33¼; third, 36⅔; in the second, 33⅓; and, in the first, 41.38, making an average of 28.6 per cent.

Agnew[2] examined 1,479 students. The ratio of myopia increased with the grade of the school, as in the previous statements, reaching an average of 28.8 per cent., nearly corresponding with the report of Zehender. In the District schools 10 per cent. were myopic; in the

[1] Archiv. f. Oph., vol. vi., p. 487.

[1] Rostock Gazette, February, 1880.

[2] New York Medical Record, 1877, xii., p. 34.

Normal High schools it reached 16 per cent., and in the Intermediate schools, 14 per cent.

In the New York College, introductory class, the myopia was 29; in the freshman class, 40; in the junior, 56, and in the senior, 37 per cent. At the Polytechnic Institute, Brooklyn, the myopia was 10 per cent. in the academic, and 28 per cent. in the collegiate departments.

Cohn, among 9,344 pupils, found the ratio of near-vision to increase from the lowest to the highest class.

In the sixth class the percentage was 22; in the fifth, 27; fourth, 36; third, 46; second, 55; and in the first, 58; making an average of the whole nearly 39 per cent.

Among 1,004 myopes, only 28, or 2.7 per cent. had a myopic father and mother.

These figures are not all, but they are sufficient to show the tendency of the eyes doing the necessary work at school to be in the direction of *increased* refraction.

A variety of measures, somewhat conflicting in certain respects, have been suggested for the purpose of preventing, or limiting as much as possible, the changes in the refractive power.

Von Reuss[1] claims that in early life the curvature of the cornea is greater, and that it lessens until the seventh year; that after the twelfth year the curvature again increases. The child is sent to school at a very early age (sometimes at four years in Germany, and at five or six years in America), when the tissues are forming and are more susceptible, because of their pliability, to outside influences than they would be a few years later. His school-days cover the period of second dentition, at which time the nutrition of the region of the trigeminus is much disturbed; his eyes are not yet accustomed to forced labor, and every deleterious circumstance makes the most of its opportunity. Constant labor, for from four to six hours a day, at close objects, often in themselves indistinct, with poor or badly regulated illumination and ventilation, enforced tiresome position, an existing slight error of refraction uncorrected, are *some* of the deleterious circumstances.

Weber, in his report on the higher schools of Darmstadt, recommends that the light should come from a point as high as the heads of the pupils standing up; that the benches should vary in size with that of the pupil; that the work should not be continued for more than forty-five minutes at a time, fifteen minutes being given to exercise; that the teachers be required to see that the work be held fifteen inches from the face; that a special physician be appointed with authority to enforce these requirements.

Derby[2] suggests that each pupil be tested every six months by the teacher, that a very early knowledge may be had of the condition, in order that he may be treated and progressive myopia avoided.

In my opinion it will be better if children are not permitted to attend the public schools until the age of second dentition is past, as the rapid progress their more matured minds will make will compensate for the time *apparently* lost, while they gain in bodily vigor and the eyes will be in a more settled condition structurally and functionally.

Objection is made by good authority[3] to *all* work requiring close vision for young children, giving as a reason, that they often leave the kindergartens myopic.

Hasket Derby's views with regard to the examination of the eyes every six months are good. The teacher might easily test the distant vision when the child enters the school; then, once in six months, and the record would be useful to the child and to school statistics.

Becoming a part of the school history, it would show the progress of each individual, as well as the changes from class to class.

The character of the materials used in the school-room has been discussed with some freedom and with varying conclusions.

Malarewsky commended to the Russian Society of Hygiene white letters upon a black background.

Cohn prefers the use of white slates, as they do not reflect, and the characters made upon them can be seen farther.

Horner advises that ink and paper be substituted for slate and pencil.

The effect of the various methods of writing has been studied, and with not greater unanimity of opinion as to what is important, or the kind of characters and the background which are most conservative.

Berlin[1] thinks slanting penmanship is the best method, the angle of the down-stroke with the perpendicular line being about 35° to 40°; that the vertical system requires more muscular exertion of the arm and forces an oblique position upon the child.

Schubert opposes the slanting system of penmanship in school, because he thinks the difference in distance of the point of fixation of the two eyes might produce anisometropia, squint, loss of binocular vision, and loss of visual power, by causing unequal accommodation.

Manz, of Freiburg, objects to inclined writing for the reason that it may assist in the causation of myopia by the unnatural attitude of the head.

Ellinger thinks the inclined method favors myopia.

Königshoefer does not agree with Berlin. He thinks the direction of the writing is not important; that the laws of the movement of the eyes act very slightly during writing; that the attitude is controlled by the desire for ease of the hand.

It occurs to me that the greatest danger is not to be found in the original work done by the pupil, as in writing on a slate or blackboard, but it exists in the effort he makes to get at the thoughts of others as expressed in print, keeping his eyes fixed upon the same character of type for a long time without relaxation.

Much more, in my judgment, is to be feared from the glazed paper, and the type unvarying in size and color, of the school text-books, read by bad light, with the body wearied by the overtaxing incident to our hot-house method of education, which so often *unfits* its victims for success in *anything* in after-life, than from any method of penmanship whatever.

Less mental work, more mental and physical recreation, with some variety in the images upon which the eyes are fixed, and in the distance of such images from the eyes will do much to obstruct the progress of the affection under discussion.

I would suggest in conclusion that in the arrangement of our school-books we should endeavor to follow the teaching of Nature, who offers us, instead of plain surfaces and flat objects, *broken* surfaces and objects differing in color, giving change in form, distance, and color. Instead of a white surface with black letters, or white letters upon a black background, it would save effort on the part of the eye if the school-books were made with *raised* or embossed letters, varying in color, printed upon an unglazed neutral surface: thus *direction* of light would have less importance.

With even surfaces, and even-colored flat objects, the ciliary muscle is kept in tonic spasm instead of healthful play, and like any other muscle when compelled to move in a fixed direction with measured force and regularity, it becomes less fitted for other efforts, as the man who has been walking over ploughed ground for a whole day will lift his feet unnecessarily high when walking upon a pavement immediately afterward.

Thus we have myopia acquisita from setting the ciliary muscle for objects at a given near point for a long time, and the *recti* muscles, being required to maintain great convergence, press upon the bulb and lengthen its antero-posterior diameter. A *plain* surface gives the idea of fixed

distance, and a great extent of snow or sand gives in nature the persistent color, unchanging light intensity and unbroken surface, the effects of which are so familiar to us.

A NEW IMBEDDING PROCESS FOR MICROSCOPIC WORK.

By MAURICE N. MILLER, M.D.,

INSTRUCTOR IN NORMAL HISTOLOGY, UNIVERSITY MEDICAL COLLEGE, NEW YORK.

BEFORE the advent of celluloidin, I had been accustomed to use paraffin for permeating and imbedding delicate tissues (where the preservation of relation of structural elements was important), and for serial sections. In order to thoroughly permeate the tissue, it became necessary in many instances to completely remove all traces of the hardening fluid by prolonged maceration in chloroform or its equivalent. This process I found to injure certain tissues, besides requiring considerable time for the removal of the paraffin from the sections. The results, however, with most tissues were unexceptionable. The sections stained readily, and were not rendered brittle; neither were relations altered.

The objections to the paraffin method apply still more forcibly to the celluloidin process, the latter requiring more than double the time occupied in the successful employment of the former. If celluloidin is to be employed, every particle of water must be removed from the tissue by prolonged maceration in ether and alcohol—twenty-four hours being frequently required. A like period is required for the thorough permeation of the celluloidin solution, and still another delay occurs while hardening. This last part of the process requires considerable tact and experience, else tissue relations are distorted by contraction of the imbedding mass. The most serious objection I have found to the celluloidin process appears after staining. The tissue is either altered or is so insulated by the surrounding mass that the stainings are pale and diffuse. Only in rare instances have I been able to secure clean, sharp differentiation with tissue that had been subjected to the celluloidin ordeal. That the tissues are altered is evidenced by their extreme brittleness seen after the imbedding has been removed.

The principal desiderata in an infiltrating and imbedding mass seem to be: First, the material should readily permeate the tissue, and that without special maceration in fluids other than the usual hardening reagent; second, it should readily dissolve from the sections without leaving them brittle; third, the process must not alter the tissue so as to modify the usual staining effects; fourth, the whole method should be susceptible of rapid execution without delay. I might add that it is desirable that the materials employed be inexpensive and easily obtainable.

My method is based on the following facts: *Bayberry tallow is firm and solid at ordinary temperatures, and is soluble in warm alcohol.*

I take a piece of tissue from the alcohol in which it is usually kept after most of the hardening processes, and, without further preparation, place it in a cup of melted bayberry tallow. The temperature need not be above what can be borne by the hand. In practice, I place the cup on one of the steam radiators used in heating the laboratory. A small water-bath, similar to the one devised by Drs. Gage and Smith,[1] and employed by them in the paraffin process, would be a convenience. Fifteen minutes will suffice for tissue ordinarily permeable, when it is removed with the forceps and placed immediately upon a cork to cool. It is now ready for cutting. Sections are made in the usual way, fastening the cork to which the tissue adheres in the microtome, or holding it in the fingers in free-hand cutting. The knife may be flooded with alcohol or kept dry, as may be preferred.

[1] Medical Student, vol. i., No. 3.

To remove the tallow from the sections they are brushed into a dish of strong alcohol, and placing the same in a water-bath, the temperature is raised to near the boiling-point of the spirit. This might seem a dangerous procedure, but the tissue is in no way injured. A second washing in hot alcohol and the sections are ready for staining. I am at present using benzole for the removal of the tallow. The sections are dropped into benzole at the ordinary temperature, and the tallow is instantly dissolved. A second rinsing in benzole is given when the sections are put into alcohol, from which they are taken for staining.

Bayberry tallow does not contract in cooling, and the relations of structural elements of tissues are most perfectly preserved. I have lately used this process with the most delicate tissues, where it was exceedingly important to preserve the parts intact, and have succeeded beyond my expectations. The sections stain perfectly, and as far as I can see, tissues are not altered in the slightest degree by the process. The benzole used for the second rinsing may be saved and used for a subsequent primary washing. It should be borne in mind that benzole is very inflammable. Should the tissue break loose from the cork, it may be re-attached with paraffin, using a hot copper wire. A piece of No. 8 wire six inches long, stuck in a wood handle, is useful for this purpose.

The tissue will keep indefinitely after having been infiltrated with the tallow, if the precaution be taken to completely cover the surface with the same.

VALVULAR FRICTION SOUNDS.

By ANDREW H. SMITH, M.D.,

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

ANY practitioner who is in the habit of studying carefully the sounds of the heart must observe cases in which the closure of either the mitral or the aortic valve gives rise to a sound which is not strictly a murmur, but which is also not the typical normal sound. The heart-sound, first or second, as the case may be, is slightly lengthened and its quality undergoes a change. The first part of the sound has the normal character, while the second, which is of the briefest duration, suggests the idea of something added. This is sometimes expressed by saying that the sound is *impure*. It was formerly, and probably still is usually, attributed to slight leakage. But the addition to the normal sound differs from a regurgitant murmur in its quality, in its shorter duration, and in the abruptness of its beginning and ending. Moreover, it is often met with in cases in which there is no other sign or symptom which could be referred to valvular lesion, and in which the history presents none of the recognized antecedents of cardiac disease. Of late the diagnostic value of these impure sounds has been called in question by different authorities, but no definite explanation of their production has been given.[1]

A careful study has led me to the conviction that they are due to a readjustment of the curtains or cusps to each other after their first contact. In the case of the mitral valve, for instance, the commencement of systole throws the curtains together, but, as the systole gains in force and the pressure of the blood becomes greater, a difference in the relative tension of the curtains would cause a slipping of one upon the other and the production of a friction-sound which, from the slightness of the motion, would be brief and abrupt. Such an inequality in the tension of the curtains would result from a difference in their area, or in the length of the tendinous cords, or in the action of the papillary muscles. In the case of the aortic valve a slight thickening of one of the cusps would occasion a similar readjustment.

[1] Scheube: Klin. Propädeutik, 1884. Friedreich: Handb. der Sp. Path. u. Ther., Virchow. 1861.

I have observed this sound at the apex most frequently in those cases in which there is an accentuated second sound at the base; or, in other words, when there is increased arterial tension. This may be explained by the greater intraventricular pressure and thus consequently increased tension of the valve-curtains. In fact, I think it will be found that in a very considerable proportion of cases of contracted kidney with increased arterial tension, the apex first sound is not pure, even though signs of decided cardiac implication may not be present.

Cases in which there is opportunity for verifying by post-mortem examination the views which I have expressed, are in the nature of things rare. Still, I can recall two cases occurring some years ago, in which slight regurgitation was confidently diagnosticated by myself and others, but in which, at the autopsy, the valve was found competent by the hydrostatic test. I now believe that in these cases a valvular friction sound was mistaken for a regurgitant murmur.

This matter is important not only as a question of nice diagnosis, but as affecting prognosis and treatment. For, if we accept a given sound as possibly indicating the beginning of valvular insufficiency, we are naturally in doubt whether the insufficiency may not increase, and in the course of time the symptoms of valvular disease be developed. But if we regard the sound as produced by friction between the valve-curtains or valve-cusps, we can more confidently give a favorable prognosis, and the restraints usually imposed upon patients with valvular insufficiency will not be considered necessary.

Clinical Department.

THE MICROPHONE IN PHYSICAL DIAGNOSIS.

Dr. Edward J. Eve, of Augusta, Ga., suggests the use of the microphone as an aid to the exploration of the various sounds produced within the human organism, not only those of the heart and lungs, but also of the abdominal viscera, of the muscles, of the intracranial circulation, the fœtal sounds, crepitus of fracture, the click of vesical calculi, etc. To the objection that there would be such a rush of confusing noises as to render it impossible to differentiate those possessing any diagnostic significance, the writer answers that practice would soon enable the ear to distinguish the pure gold from the dross. He admits that many difficulties must be surmounted before the instrument can be so perfected as to be of practical utility, but predicts that patient endeavor will in time overcome them all, and that the microphone will be found capable of being converted into an instrument whose application will be the most wonderful and useful in the whole realm of acoustics.

SPLENIC LEUCOCYTHÆMIA—AUTOPSY.

Dr. Lyman Rogers, of Remington, Vt., relates the history of a man, aged forty-six, who came to him in August, 1884, suffering from leucocythæmia. Four years before he had had typhoid fever, and had never been quite the same since. In November Dr. Rogers examined the blood and found diminution in red-blood cells but no increase in the white cells. The disease pursued a rapid course, and the patient died of asthenia on January 1, 1885. Dr. Rogers continues: "Post-mortem at 3 P.M. Was only permitted to open the abdomen. Body very much emaciated. Found the visceral peritoneum roughened by exudation; liver five inches too low; spleen enormously enlarged, and the lymphatic glands everywhere hypertrophied. Considerable accumulation of serous fluid in the cavity of the abdomen. The spleen weighed six pounds twelve ounces. Its fibrous coat was covered with nodules three millimetres in diameter, and was thickened; consistency of the organ normal; there were two or three infarctions. The liver weighed eight pounds eight ounces; consistency, normal; color, rather pale. Kidneys and pancreas normal. Mesenteric glands are enlarged, the largest was two inches long. I brought away some blood to examine. Found the red globules as before described, they still preserved their integrity; the white globules were largely increased in number. By diluting and connecting different fields I obtained an average of one white globule to ten red. Microscopical examination of the spleen, enlarged glands, liver, kidneys, and pancreas showed the tissues crowded with white-blood cells. The organs appeared otherwise normal, except the kidney, in which the epithelium of the large tubules was detached and broken down; I found no heteroplastic glandular deposits.

"In reviewing this case I find three noticeable features. First, that it seemed to follow the attack of typhoid fever; next, that his skin and mucous membrane did not become pale until almost two weeks before his death, and the excess of white corpuscles must have developed very late in the disease; and last, that there were no enlarged glands in the neck, axilla, or groin. I am compelled to regard the typhoid fever as an important element in the causation of his disease. The influence of such a fever, when severe and protracted, upon the nutrition and functions of the parenchymatous organs, and especially of the hæmotopoietic viscera, is well known. As to the late development of anæmia and excess of white globules—following after the splenic hypertrophy—it seems to point to that as its cause. So that I would regard this case as serving to confirm the theory of Virchow as to the nature and etiology of this disease."

Progress of Medical Science.

Tumors of the Pituitary Body.—Pathological anatomy affords abundant illustration of the principle that morbid action is prone to occur in tissues and organs which have ceased to take any important share in the physiology of the economy. At the London Pathological Society several new growths of the pituitary body were recently exhibited (*Lancet*, February 7, 1885). The development of the hypophysis cerebri, or pituitary body, as it is commonly called, has been the subject of considerable controversy among embryologists. Von Baer and Schmidt taught, in 1862, that the whole of the gland was developed at the expense of the infundibular process at the floor of the third ventricle. In 1838 Rathke stated that a diverticulum from the upper end of the alimentary canal shared in the formation of the hypophysis. Dursy made the pituitary body to be formed out of the end of the notochord, as well as of the epithelium of the alimentary tract. Reichert at first believed this structure to be developed from the remains of the front end of the notochord, but later on he considered that the pia mater was chiefly involved in its formation. Rathke also modified his earlier views, and came to believe that the diverticulum of the alimentary canal disappeared, and that the hypophysis cerebri was developed from a portion of the mesoblast, in front of the clinoid process. Wilhelm Müller wrote an elaborate memoir on the development of the pituitary body, in which he made out that a hypoblastic diverticulum from the upper end of the alimentary tract joined the infundibulum from the third ventricle. Götte and others, however, believe that the epiblast of the stomodæum is concerned in the formation of the diverticulum which goes to meet the infundibular process, and this was the view which Mr. J. B. Sutton adopted at the discussion before the above Society. The specimens of the myoneuroma shown by Dr. Hale White contained abundant nerve-cells and striped muscle fibre. The mesoblast around the upper end of the alimentary tract is no doubt the source of these striped muscle fibres, and the explanation proffered by Mr. Sutton, that a larger amount than usual of nipping off of the epiblast took place, is very reasonable.

Hysterical Pyrexia.—Ancient authors used to allow the existence of hysterical fever, and though this idea has been ridiculed by modern authorities, yet recently M. Debove has advocated it afresh. He believes that he has seen several examples of it, although where febrile movements are recorded in hospitals for nervous females we might suspect the onset of tuberculous disease. A case was narrated by M. Debove (London *Lancet*, February 28, 1885), which he watched for five years after the commencement of the pyrexia. The patient was twenty-four years of age, and had suffered from neurotic disturbances ever since the age of seven years. Three years ago she suffered from a severe febrile disturbance, which exhibited the three stages of cold, heat, and sweating, very clearly; since that time the temperature, taken at regular intervals, has never been below 100° F., and two or three times a week the temperature has intermittently reached to nearly 104° F. The possibility of malaria was excluded by M. Debove, on the ground that the spleen was not enlarged, and that quinine had no influence over the fever. Deception seemed to be out of the question, as M. Debove himself took the temperature on several occasions. The question was discussed at the Académie de Médecine whether in hysterical individuals the heat-centres might not be functionally disturbed, thereby occasioning the alterations in the normal heat of the body —whether, in fact, hysteria of the thermic centres is possible.

A New Method of Treating Acute Intestinal Obstruction.—There has recently been advocated and successfully practised a method of affording relief in cases of intestinal obstruction, which may become widely applied. Dr. Kussmaul was the first to advance the view that free washing out of the stomach might prove efficacious, and already cases of marked success following this measure have been published. In one case, after eight days' complete obstruction, and in the other, after nine days, the symptom of fecal vomiting being present in each, the washing out of the stomach, and consequent evacuation of large quantities of fluid fecal matter from the upper part of the small intestine, resulted in complete relief from symptoms. The measure is compared by Cahn to the effect produced by laparotomy above the site of an obstruction; and the good result is explained on the ground that the evacuation of the distended bowel affords an opportunity for a spontaneous reduction of a herniated or twisted loop. The relief from the inordinate abdominal distention is very great, and, moreover, the disappearance of this distention favors palpation for the purpose of diagnosis. Obviously, not every case of acute intestinal obstruction could possibly be relieved by this method, but the simplicity of the practice, the certainty of affording temporary relief, and the possibility of a cure are reasons for its sedulous adoption prior to proceeding to more serious measures.—*Lancet*, February 14, 1885.

The Treatment of Intestinal Invagination by Washing out the Stomach.—Prof. Kussmaul has done this in several cases, and has almost always found the relief to be immediate and lasting; the treatment being specially applicable to cases where, the exact position of the lesion not being known, more energetic operative interference is inadmissible. The chief advantage of removing gas and fecal matter from the stomach is, that more room is thereby attained in the abdomen; and the digestive tract, being relieved from distention in its upper part, can more easily overcome the pressure and displacement at the seat of invagination. The exaggerated peristaltic action, too, is reduced to the normal, and an increase of the evil thereby avoided. If morphia have not already been administered, it is well to preface the operation with a subcutaneous injection; but it is found that the passage of the soft tube, which ought to be employed, causes less distress than the vomiting and straining induced by the lesion.—*London Medical Record*, February 16, 1885.

Extirpation of the Kidney.—Prof. von Bergmann, of Berlin (*Centralbl. für Chirurgie*, No. 45, 1884), says that this operation is no longer a rare one; for, since Simon's first case, it has been performed one hundred and twenty-one times. It may be indicated in a case of malignant tumor, or in one of pyelo-nephritis. In the former class of cases the operation is a very dangerous one, as it is necessary to perform laparotomy, and to make a double incision of the peritoneum. Moreover, a suppurating cavity may be formed behind the peritoneum, and discharge its contents into the abdominal cavity. Important mesenteric vessels are often divided, and thus a risk of gangrene of intestine is set up. Of twenty-four cases of operation of this kind, in seventeen death occurred during or soon after the operation, in five of which it was due to hemorrhage. Only four patients recovered. In cases of cancerous disease of the kidney, metastatic and disseminated growths are usually found at the time of operation in the intraperitoneal and mesenteric lymph-glands. Extirpation of the kidney has had much better results in cases of pyelonephritis, as of forty cases twenty have been cured. In one case, Von Bergmann attempted to attain a cure by simple incision of the numerous abscesses, but without success, as the suppuration persisted. The kidney was finally extirpated with a good result. In the course of twelve months he extirpated the kidney four times, in each case with success.

The Inhalation of Salt in Chronic Pulmonary Affections.—Dr. A. Tobold recommended some years ago the use of a salt spray in the sleeping apartments of those suffering from chronic inflammatory affections of the respiratory organs. There were many difficulties, however, in the way of this application, and now the author advises the insufflation of dry salt in very fine powder. This has the advantage over spray, that it penetrates more deeply into the respiratory passages. Two applications are made daily, and at each sitting ten or twelve deep inspirations of the salt powder are taken (*Schmidt's Jahrbücher*, No. 8, 1884).

Some Recent Observations on the Treatment of Dysentery.—The good effects of various remedies in the treatment of dysentery are frequently questioned by writers of large experience. On the other hand, there are those who insist on the power of drugs to cut short an attack of the disease. Among recent contributions to this subject we find the following: Dr. Seaton is very emphatic as regards the utility of ipecacuanha powder. The remedy, though an old one, is thought by many practitioners to be applicable rather to the tropical forms of the disease, than to the dysentery of our climate. Dr. Seaton, however, considers ipecacuanha the best medicament against the disease, and administers it as follows: 1, Abstinence from liquids for two hours; 2, introduction into the rectum of an opium suppository; 3, application, twenty minutes after, of a poultice of linseed-meal and mustard over the epigastrium; 4, ten minutes after, the administration of forty grains of the powder of ipecacuanha root, in a biscuit or in wafer, which is followed by a tablespoonful of milk or rice-water, to aid its deglutition; 5, the patient is recommended to keep the recumbent position for two hours at least, abstaining from any drink. Administered in this manner, this medicament has been, in the author's hands, in hundreds of cases, as efficient as quinine in malarial fevers. Dr. Rosenfeld employs and recommends iodized phenol, especially for the dysentery of children. The drug consists of a solution of about four grains of pure iodine in one and one-quarter ounce of glycerine, to which about four grains of carbolic acid are added. One to two teaspoonfuls of this mixture are administered three or four times a day in a glassful of water as an enema. A sensation of warmth in the abdomen is followed by a substitution of green stools for the former bloody ones, and in the course of a day or two the only remaining trace

of the malady is a slightly mucous diarrhœa. In a severe epidemic of dysentery, in which eighty per cent. of those attacked were under ten years of age, and forty-nine per cent. between one and three years of age, only 6 died out of 142 treated in this way. According to the *London Medical Record*, March 15, 1885, Dr. Schtchegloff, of Jisdra, Kaluga Government, has tried carbolic enemata in twelve cases of acute dysentery, and obtained most striking results. Six of the patients (all peasants and soldiers) left the hospital after three days' treatment, three after four days, one after six days, one after nine days, and one after ten days. In two of the cases the carbolic treatment was resorted to after other means (calomel, starch, and opium enemata, tartaric acid, etc.) had failed. In the remaining ten, the patient on his admission had six drachms of castor-oil, as well as wine and tincture of valerian (according to the state of his pulse). On the next morning an enema, made of six or seven pints of a carbolic solution (1 to 500), at the temperature of 27° R. (92.75° F.), was administered. In all the cases, within a few hours after the first enema, there was observed a decrease of the temperature and a great diminution of abdominal pain and tenderness; then the stools rapidly lost their dysenteric character, and after one or two pure diarrhœa stools, soft sausage-shaped and normally colored excrements followed. The author never observed any awkward accessory effects from the treatment. Dr. Schtchegloff tried also the treatment of dysentery by the internal administration of carbolic acid, but its success was only very moderate. The perusal of Dr. Schtchegloff's article induced Dr. Kampf, of Oster, Tchernigov Government, to try (*Russkaia Meditz.*, No. 48, 1884) the plan recommended by the former in eight cases of acute dysentery (three in hospital practice, five in private). Three hospital cases (peasants) were very severe. The treatment was commenced on the fifth, sixteenth, and twelfth days of the disease. The enemata (made of 1 part of the acid to 500 of water) were administered twice or three times daily, at the same time an emulsion of castor-oil and resorcin being given. The results were as brilliant as in Schtchegloff's cases. All three patients left the hospital after four days' treatment. Five cases in the author's private practice were all cured after two or three carbolic enemata. Feeling encouraged by his own and Schtchegloff's remarkable success, Dr. Kampf recommends carbolic acid as a specific remedy for dysentery. If carbolic acid be employed in dysentery the fact of its possessing toxic properties should never be lost sight of. That the drug is not a specific for dysentery, as believed by Kampf, need hardly be mentioned. It is probable that simple injections with warm water are safer than carbolic-acid enemata.

Persistence of the Foramen Ovale.—The following condition was found at the autopsy of a patient dead of phthisis in the Rudolph-Stiftung of Vienna (*Bericht vom Jahre* 1883). The foramen ovale was completely patent, measuring four-fifths of an inch in diameter, and its borders were somewhat thinned and perfectly smooth. The pulmonary artery was nearly as wide again as the aorta, and the pulmonary valves were correspondingly greater than the aortic. There was also marked dilatation of the right auricle and ventricle, as well as hypertrophy of the walls of the latter. The heart was displaced to the right side by reason of an induration and retraction of the right lung.

Phantom Tumors.—The case is related by Dr. Krukenberg of an hysterical woman twenty-four years of age, whose abdomen was very large and tense, giving the appearance of a tumor. This was present when the patient lay down as well as when she stood, but when she was placed under chloroform, the abdomen became soft and flat. The author remarked later that the patient had a marked lordosis of the lumbar vertebræ, with a posterior bowing of the dorsal spine, which he thought was due to weakness of the muscles of the back, arising from the long confinement in bed. The lordosis of the spine caused increased intra-abdominal pressure, and thus the intestines pushed out the weakened abdominal muscles. This condition persisted while the patient lay in bed, and and it was only when she was raised to the kneeling posture that the lordosis, and with it the phantom tumor, disappeared. Why the lordosis should persist during the maintenance of the recumbent posture is not very clear, though Dr. Krukenberg thinks that the abnormal position of the vertebral column had caused a gradual shortening of the spinal muscles.—*Schmidt's Jahrbücher*, No. 8, 1884.

A Case of Central Respiratory Neurosis.—A man twenty-three years of age, in fair general health and apyretic, was admitted to hospital suffering from very frequent respiration. These were sixty to the minute, very shallow, and occurred without any expansion of the thorax. There was a sinking in of the supraclavicular region, with slight raising of the epigastrium at each inspiration, and the shoulders were a little elevated. The movements of the nostrils were very apparent, as in a severe case of pneumonia. The respiratory sounds were very weak, but plainly vesicular after coughing. The voice was gone, and an audible tone could be emitted only on great exertion. Laryngoscopic examination showed a separation of the vocal cords of about one-tenth of an inch during phonation. Nothing else abnormal was found. The patient stated that the trouble began five years before, and was caused by a fall from a considerable height. He struck on his head and neck, and the rapid respiration was at once noticed. The symptoms had become less severe after about three years, but for the last year had been again growing worse. A slight improvement followed galvanization in the distribution of the cervical sympathetic.—*Bericht der Rudolph-Stiftung vom Jahre* 1883.

A Peculiar Effect of Digitalis upon the Eyesight.—The case is related in the *Bericht der Rudolph-Stiftung vom Jahre* 1883, of a man suffering from heart-disease following rheumatism. The urine contained a small amount of albumen. The patient was placed upon three grains of digitalis leaves, in the form of infusion, per diem. About a fortnight later the man complained of weakened vision, there seeming to be a cloud before his eyes. He attributed it to the digitalis, saying that he had been affected in the same way on a previous occasion while taking the drug. He could see better in the evening than by daylight. The pupils were not especially dilated, and nothing abnormal about the eyes could be detected on examination. There were no other symptoms of digitalis poisoning, such as nausea, etc. The administration of the drug was discontinued, and in a few days there was a marked improvement in the sight.

Parasitic Fibromata of the Skin.—A case is related by Professor Pio Foà of a man, forty-six years of age, who suffered without any apparent cause from cutaneous tubercles, appearing first on the right foot and extending, during the course of seven years, over various parts of the body. The tubercles ulcerated, secreted pus, and then healed, leaving flat cicatrices having no resemblance to the deforming and depressed cicatrices of syphilides. The patient died after amputation of the penis. At the autopsy were found œdema of the brain, sub-pleural and sub-pericardial ecchymoses, cloudy swelling of the myocardium, liver, and kidneys, and congestion of the spleen. The bones of the hands were denuded of their periosteum and had lost their normal consistency; some were swollen and could be readily cut with a knife. The cutaneous tubercles were found to be histologically fibro-sarcomata, but the progressive and malignant nature of the disease led Dr. Foà to suspect a parasitic cause. Treated by Ehrlich's method, all the preparations showed numerous granular micrococci isolated and arranged in groups.—*Lo Sperimentale*, February, 1885.

Inflammation of the Pulmonary Artery.—In an elaborate article on this subject appearing in the *Archivie delle Scienze Mediche*, vol. ix., No. 2, Dr. Rattone formulates the following conclusions from a study of upward of fifty cases: 1. Pulmonary arteritis may be either acute or chronic (atheroma), the latter being the more frequent. 2. It may be primary or secondary, the primary form not leading to cirrhosis of the lungs. 3. The cases seen by the author of acute arteritis had their origin from a primary inflammation of the semilunar valves. 4. Chronic inflammation or atheroma may be met with in any portion of the pulmonary artery, but is more often seated in the vessels of medium size, and especially at their points of bifurcation; it is distributed symmetrically in the two lungs. 5. In this disease there may be seen not only the atheromatous patches, but also abscess, ulceration, and in some cases calcification. 6. Pulmonary atheroma is entirely independent of a similar disease in the aorta; it may coexist with it, may exist without it, and may be absent when the aorta is profoundly diseased. 7. Pulmonary atheroma is met with constantly in mitral stenosis which has occasioned a certain degree of hypertrophy of the right heart; but may also be found with stenosis of the aortic orifice, in cor bovinum and other congenital defects. 8. The disease may occur in young subjects who have never suffered from heart-disease. 9. Atheroma of the pulmonary artery is a frequent cause of hemoptysis, and may also give rise to thrombosis and hemorrhagic infarction. 10. Finally, as regards the cause of atheroma, the author agrees with Martin that it is secondary to arteritis of the vasa vasorum.

Acute Pancreatitis in Childbed.—Dr. R. Haidlen relates the case of a primipara, thirty-three years of age, who had suffered during pregnancy from gastric disturbances and headache, and during the latter part of this period from severe colic and slight symptoms of peritoneal irritation. Owing to weak labor pains delivery was effected with the forceps. During the following three weeks the progress of the case was normal, but at the end of this time there were occasional hemorrhages, and several attacks of pain in the gastric region. The last of these was very severe and accompanied by vomiting. There was no fever, the pulse was 100 and regular. There was great tenderness on pressure over the pit of the stomach. The intellect was unimpaired. The urine was voided normally, but in small quantities; the bowels did not move. Finally, the pain in the epigastrium became very severe, meteorism set in, the extremities became cold, and the patient died. At the autopsy the pancreas was found to be enlarged in all its dimensions and of a brownish-red congestive color, the result of acute inflammation. There was no marked peritonitis, and the other organs were normal.—*Schmidt's Jahrbücher*, January 29, 1885.

Kussmaul's Coma.—The group of symptoms which have been designated by the inexact name of "Kussmaul's coma" consists chiefly of slow and labored respiration, rapid cardiac action, restlessness and pain, apyrexia, glycosuria, and paralytic distention of the stomach. An article, containing a large amount of information on the literature of this subject, has been written recently by Dr. Saundby. There seems to be no doubt that this group of symptoms may be met with in morbid states of the system unaccompanied by glycosuria. That the symptoms are caused by a poisoned condition of the blood seems most probable. It may be well to point out that two of the chief symptoms may be explained on the assumption of paralysis of the vagus nucleus. The slow and labored respiration somewhat resembles that form of dyspnœa which is the result of section of both vagi; the acceleration of the heart's action might be attributed to the more or less complete removal of the inhibitory cardiac functions of the vagus nucleus. Whether damage of the vagus nucleus can determine paralytic distention of the intestines must remain a purely speculative question. Epigastric pain or distressing sensations about the epigastrium have been referred, in epileptic seizures, to central disturbance of the vagus paths. We have not the least bias in favor of the supposition that all the symptoms of so-called Kussmaul's coma are due to interference with the vagus nucleus, though it may be well to consider the claims of such a suggestion. Alkaloids have a selective action on many parts of the nervous system, and there is the bare possibility that Kussmaul's coma may be the work of some alkaloid having a selective action on the vagus centres.—*Lancet*, February 21, 1885.

Spontaneous Fracture.—At a meeting of the Surgical Society of Paris (*Journal de Médecine et de Chirurgie Pratiques*, March, 1885), M. Humbert related the case of a young man, eighteen years of age, who had severe pain in the upper part of the thigh, accompanied by a considerable swelling in that region, and shortly afterward presented all the symptoms of a fracture of the femur. There had been no traumatism. The diagnosis made at the time, by all who saw the patient, was that of osteo-sarcoma with spontaneous fracture. However, some time afterward the swelling began to diminish, union took place, and the patient was able to leave the hospital. M. Humbert then concluded that the case was not one of osteo-sarcoma but of osteomyelitis. M. Verneuil suggested that there might have been an hydatid cyst of the bone, especially as the speaker had said that there was at one time a discharge of fluid from the swollen tissues. M. Duplay said that he had had a case in which spontaneous fracture occurred several times, and each time union took place. Finally the limb was amputated, and the femur was found to be considerably atrophied and to be the seat of numerous hydatid cysts.

Pulmonary Rheumatism.—In a recently published thesis, M. Lebreton presents the results of his studies on the pulmonary manifestations of rheumatism. These may occur, he states, independently of any articular affection, in subjects who have previously suffered from rheumatism, or who come from a rheumatic family. Pulmonary rheumatism occurs under two distinct forms, the pneumonic and the œdematous. The former is not necessarily associated with a cardiac implication, but may occur when the heart is unaffected. The facies in this form is peculiar, and does not at all correspond to that of ordinary acute pneumonia. The face is pale, and it, as well as the entire body, are bathed in profuse acid perspirations. The stethoscopic signs are fugitive, and may be located at the right apex to-day, and to-morrow may be at the left base or may have disappeared entirely. In the œdematous form the symptoms vary greatly in intensity. There is first difficult respiration, the face is pale, the body is covered with perspiration, the chest is filled with râles, indicating a general bronchitis. The heart is normal. Sometimes the symptoms come on so suddenly and with such intensity that the patient may be carried off in a few minutes. In addition to these two distinct types there are frequently pulmonary manifestations of rheumatism under the form of congestion. Of these three clinical varieties are to be noted: 1. Hæmoptysis. In rheumatic subjects there may be frequent and profuse hemorrhages from the lungs without any tubercular trouble. 2. The remittent form. Here we meet with remittent or intermittent attacks of dyspnœa, more severe at night, and due solely to rheumatic congestion of the lungs. 3. The latent form. This is characterized by the single symptom of a peculiar sound, resembling the crepitant râle of pneumonia, heard in inspiration and most frequently in the right axillary line at the junction of the upper and middle third. The treatment of pulmonary rheumatism consists in the administration of salicylate of soda or of iodide of potash for the persistent manifestations, and of sulphate of quinine for the hemorrhagic and remittent forms.—*Revue Médicale*, February 28, 1885.

The Medical Record:

A Weekly Journal of Medicine and Surgery.

New York, April 18, 1885.

THE EXTERNAL TUBERCULOUS AFFECTIONS.

Perhaps the greatest achievement of modern pathology is its discovery of the intimate nature and clinical characters of tuberculosis in all its forms. Since 1810 the conception of the tubercle and of tuberculosis has undergone very remarkable changes. Within the last few years, even, there have been contributions made to the subject that have revolutionized again the views concerning it. The tubercle of tuberculosis now is known to be a specific, infective, inflammatory, non-vascular nodule, holding a parasite in its substance. It attacks not only the lungs, but all mucous and serous membranes, while every organ in the body may be affected by it. The tubercle appears either as a focal or a general disease. When limited to foci there is always the possibility of its spreading and involving other parts of the body. This "infective granuloma" tubercle, is, by all odds, the most serious enemy of the human race, not only because of its causing phthisis, but because it slays its thousands and tens of thousands in other ways also. For the discovery of the infectiveness of tubercle and of its diagnostic sign, the bacillus, has shown positively that various diseases of joints and bone (*e.g.*, tumor albus, scrofulous ostitis), cold abscesses, scrofulous swellings, caseous forms of adenitis, ulcerations of mucous membranes, etc., are as truly tubercular as are the processes of pulmonary phthisis.

It will be a great advantage to the profession when it clearly understands that tuberculosis can show itself in such manifold ways, and that there is essential unity in all its manifestations. Dr. Roswell Park, in the "Annals of Surgery," has recently done good service in calling attention to this matter and in giving an excellent summary of the present knowledge regarding tuberculous surgical affections. Before referring further to Dr. Park's article it is well to state at once that the term "surgical tuberculosis," which has lately been much used, tends to confuse the general reader and had best be abandoned by scientific writers. If we have a surgical tuberculosis, there will soon be a medical tuberculosis, which is manifestly absurd. Tuberculosis is tuberculosis wherever it may be. However, when it is accessible to the knife it is at present termed "surgical." Those forms of tuberculosis with which surgeons have to deal are classified by Chavot as follows :

"1. Cutaneous tuberculosis—well-known—lupus being perhaps the best example. 2. Tuberculosis of mucous surfaces; ulcerations of the tongue, mouth, larynx, intestine, anal fistula, etc. 3. Tuberculosis of subcutaneous or intermuscular connective tissues—nodules, cold abscesses, etc. 4. Periosteal tubercular nodes, known as sub-periosteal cold abscesses (Duplay), chronic periostitis (Follin), periostitis externa (Gaujot), and chronic suppurative osteo-periostitis. 5. Various forms of tuberculosis of bone, known commonly as caries, necrosis, chronic ostitis, scrofulous ostitis, etc., which lead to the formation of so-called 'congestive abscesses' and 'wandering abscesses.' 6. Tuberculosis of joints, the common tumor albus, fungous tendo-synovitis or tendo-vaginitis. 7. Tuberculosis of the genito-urinary tract—testis, epididymis, cord, prostate, bladder, uterus, ovaries, etc. 8. Tuberculosis of glands—the various chronic, caseous, or suppurating forms of adenitis."

In the natural history of tubercle, four stages are observed: 1. That of tubercular infiltration; 2, that of caseous or puriform degeneration; 3, that of elimination or absorption of products of degeneration—stage of ulcers, fistulæ, fungosities, etc.; 4, reparative stage. Naturally it is not in all cases that the disease runs through all these stages, and it may indeed be much more advanced in one part of the body than another. Some interesting facts are noted with regard to the first stage, or period of infiltration :

Tuberculosis of mucous surfaces accessible to the surgeon begins by nodosities, in very limited patches and by layers of diffuse infiltration.

Tuberculosis of subcutaneous or other intermuscular connective tissue takes for the most part the circumscribed form of tubercular gummata, well described by Josias and Lannelongue.

Tuberculosis of periosteum commonly occurs in caseous masses, varying in thickness and extent, or in isolated masses of the size of a hemp-seed. They form, for the most part, in the deeper layers, where there is greater vascularity. By pressure they assume a discoid shape.

In the genito-urinary tract, as Cruveilhier long since showed, there are two favorite sites for the formation of tubercle, viz., the prostate and the epididymis, the testis being in the immense majority of cases only secondarily involved. In the cord the process usually goes on more slowly, by preference at the extremities.

In tuberculosis of lymph-glands the initial alteration presents certain peculiarities which make it at first less characteristic, and may thus mask its specific nature. In many cases the gland swells, hardens, and presents on sections gray granulations, which contrast with the reddish lymphatic tissue. When these do not appear so prominently, the tissue, under the microscope, will seem studded with giant-cells and specific follicles; the infiltration will then be less evident to the naked eye than when caseous masses appear.

In bone, where it is most easy to study tuberculous processes from their inception, the lesions are spoken of as the encysted and the infiltrated. The encysted form was first properly recognized. The lesion develops in the osseous—usually the cancellous—tissue grayish granulations, fusing into grayish masses, having fibrous envelopes separating easily from their surroundings, gradually congesting around the periphery. They do not join

at first, but remain some time separated by the osseous trabeculæ. But these partitions rapidly disappear, the tubercles agglutinate together, thus forming masses which are not slow to succumb to caseous degeneration.

The other variety of tuberculosis of bone is the circumscribed infiltration, corresponding to Nélaton's "semi-transparent," or "puriform," or "opaque" infiltration.

Tuberculosis of joints may be primary or secondary. It is primary when it begins in the synovialis and invades in succession the cartilages and the bone; secondary when the infection is by the opening into a joint of a focus in the epiphysis.

Passing over Dr. Park's analysis of the other periods we have only space to refer to the important subject of etiology and treatment. Under the former head we have as predisposing causes:

1. Age.—Tuberculosis certainly is most common in early life; beyond the thirtieth or fortieth year of life it is more rare, but still not exceptional. A so-called "senile scrofula" has been described by some authors, which is nothing else than a tuberculosis of old age. Adenitis and tuberculous gummata, ostitis and tumor albus, are most frequent in childhood; tuberculosis of the genito-urinary tract in adolescence and old age. This is all explained by the order of development of the respective parts affected. 2. Sex.—Scrofulous affections are slightly more common in the female sex. 3. The "lymphatic" temperament. 4. Heredity. 5. Bad hygienic conditions, such as bad air and moisture. Imprisonment exerts no small influence in this direction. In fact, prisons are too often depots for tubercular infection; military barracks are not much better. For a long time military surgeons have noted the progress of cold abscesses among patients in army hospitals.

The two main exciting causes are traumatism and chronic inflammations.

As regards treatment Dr. Park gives this brief summary: "The methods of treatment suitable to the character of the troubles under consideration may be summed up under five headings, brief mention of which must here suffice: 1, Expectancy; 2, destruction of the tuberculous focus by fluid or solid caustics; 3, curetting or scraping out the sinus, abscess, or cavity; 4, extirpation of the tuberculous focus, enucleation, resection; 5, amputation of the limb or organ affected.

"These plans will be pursued in the order above given just in proportion as we learn that surgical tuberculosis is not an incurable affection. That this is a fact many cases of recovery teach us."

GENERAL GRANT'S CONDITION.

During the past week General Grant has suffered from considerable irritation about his throat, and the secretion of mucus has, for the time being, been increased. On two or three occasions he has had attacks of choking, which depended as much on reflex spasm as upon the temporary accumulation of phlegm in the larynx. At no time has he been in imminent danger of suffocation. The local disease has made no progress except to a slight extent along the free border of the right side of the velum. The sloughy exudation in the vault of the pharynx is beginning to disintegrate, and portions have been discharged, exposing a characteristic fungoid granular surface underneath. The chances of the mass, in its separation from the throat surface, temporarily obstructing the larynx, have thus been removed. In consequence of this change, also the local condition has greatly improved.

The glandular swelling has not perceptibly increased, although the surrounding inflammatory changes give rise from time to time to pain on pressure. The pain in swallowing is not so great, but the difficulty in deglutition is sometimes quite marked, owing to the loss of tissue in the velum. The granular infiltrated condition of the palatal curtain still exists, and by the extension of the irritation of its presence the neighboring tissues temporarily become more or less œdematous, explaining the reason for a hemming cough with which the distinguished patient is often very much annoyed.

His general condition is much improved. His food, which is of the most nourishing kind, is well assimilated, and his bodily vigor has of late been but little impaired, considering the number of recent drawbacks he has experienced.

The smallest amount of morphine is given consistent with overcoming pain and inducing needful sleep. During the past few days but six minims of Magendie's solution have been injected hypodermically in the twenty-four hours.

LUSTGARTEN'S BACILLUS OF SYPHILIS.

Some time ago we gave an account of the claims made by Dr. Sigmund Lustgarten to the discovery of a specific micro-organism of syphilis. Dr. Walter Wyman has forwarded to the *Maryland Medical Journal* a translation of a communication made on March 27th to the Imperial Society of Physicians of Vienna, in which Lustgarten gives a description of the methods which he has used in discovering his bacillus. This method is as follows:

"Sections which have been hardened in alcohol are colored in a solution of gentian violet from twelve to twenty-four hours at the ordinary temperature, and then for two hours at a temperature of 104° Fahrenheit.

"The section, in order to be decolorized, is first washed in absolute alcohol for several minutes, and then by means of a glass or platinum needle conveyed into a watch crystal containing about three cubic centimetres of a one and one-half per cent. aqueous solution of permanganate of potash. In this it remains about ten seconds. As a result, a brown, flocculent precipitate of the hyperoxide of manganese is formed in the fluid and also covers the sections. It is then placed in an aqueous solution of chemically pure sulphurous acid, in which it is deprived of the hyperoxide of manganese either instantaneously or in a very short time, dependent on the concentration of the acid. It now appears entirely rid of its coloring matter in some places, while in others it is still deeply colored. It is next washed in distilled water and is again placed in the solution of the permanganate of potash, in which, as in the succeeding repetitions, it remains three or four seconds, and from it is again conveyed to the sulphurous acid.

"When it appears colorless, which as a rule occurs af-

ter this procedure has been gone through with three or four times, it is dehydrated in alcohol, rendered transparent in clove oil, and mounted in Canada balsam (xylol Canada balsam the best).

"This method of decolorization not only permits the micro-organisms of syphilis to be brought to view, but is a characteristic staining reaction for them. The bacilli of syphilis, tuberculosis, and leprosy, are distinguished from all other known bacilli in that they are not decolorized by my method. The bacillus of syphilis is distinguished from that of tuberculosis and of leprosy by the fact that the syphilis bacillus is decolorized by nitric and hydrochloric acid, while the bacilli of the other two are not."

By means of the method described, Lustgarten examined syphilitic lesions in sixteen cases. The bacilli were found to be present in initial lesions, in papules, and in four products of the tertiary stage; in other words, in all the stages of the syphilitic process. On the other hand, in two chancroids examined, the characteristic organism was not found. The bacilli were never free, but always enclosed in cells resembling lymphoid cells, and probably capable of movement. They appear as straight or curved and sometimes irregularly bent rods, which are on an average from three and one-half to four and three-tenths of a micromillimetre thick. With a low power they appear uniformly smooth, presenting here and there a bulbous swelling at their extremities. With a homogeneous immersion lens ($\frac{1}{20}$ inch Reichert) their surface appears irregularly undulatory and slightly notched, yet in a manner that leaves no doubt as to their rod nature. Within them one recognizes, at equal distances from one another, oval, colorless, bright spores, from two to four in every bacillus.

No cultivations or attempts at inoculation have yet been made. The bacillus, therefore, if it is a constant accompaniment of syphilis, has as yet been shown to have only a diagnostic importance. The establishment of Lustgarten's claims will at least serve to close forever the controversy as to dualism and unicism.

IS THERE A SYPHILITIC PHTHISIS?

While it is well known that syphilis may affect the lungs, it is still a question whether a true phthisis, or wasting disease, in which the syphilitic process goes through analogous changes to the tuberculous process, really exists. Hiller (we quote from the *Boston Medical and Surgical Journal*), after a critical study of the literature of the subject and of some cases of his own, comes to the conclusion that there is no scientific proof of the existence of a syphilitic phthisis. The anatomical changes in the lungs traceable to syphilis are scars, gummata, and chronic indurations, while the clinical histories ordinarily obtained from these conditions are those of lung tumors or chronic interstitial pneumonia. This much is granted by Hiller and is generally accepted regarding syphilis of the lungs.

At a recent meeting of the Clinical Society of the Post-graduate School, Dr. William Henry Porter made some radical, and by no means well-substantiated, statements regarding syphilitic phthisis. This affection, he thought, not only exists, but is not uncommon. It was most frequent at the apex; in the early stage it was a pneumonic process, but later formed cavities. The rational signs were often those of ordinary phthisis, but the physical signs were peculiar. The diagnosis was to be based upon the history of a phthisis without much emaciation, upon the presence of a peculiar tenderness over the sternum and tibia, excessive dyspnœa, hæmoptysis, little or no rise of temperature, and upon the effect of treatment.

Dr. F. R. Sturgis, at the same meeting, expressed the view that syphilitic phthisis was not a common affection. When it occurred it could be distinguished from tubercular phthisis by the absence of emaciation and hectic, and by the discovery of diffused dulness in the lower part of the lung, rather than the apex. Dr. Sturgis thought that hæmoptysis rarely occurred, and doubted the value of antisyphilitic treatment as sure proof of the character of the lesion.

To show further the contradictory views as to the clinical characters of syphilis of the lung, we quote from Dr. Hiller again, who says that the diagnosis can never be made with certainty, and that the dyspnœa, cough with scanty expectoration, and other symptoms and signs, are not characteristic. The diagnosis is to be based upon the history of the case, the presence of other recognizable syphilitic lesions, and upon a laryngoscopic examination, which will reveal, in nearly all cases, old lesions of the upper air-passages.

In this connection an interesting observation has recently been made by Henri Gaudichier at the Hôpital St. Louis, service of Professor Fournier.

A man, aged thirty-nine, entered the hospital with well-marked nodes, and a history of syphilis. He had a cough, and had emaciated considerably. Examination showed distinct signs of a good-sized cavity at the apex of the left lung, with dulness and crackling râles on the right side. Fournier pronounced it a case of syphilis with a tuberculous cavity in the lungs. The patient was placed upon an antisyphilitic treatment (℥j. of potas. iodide daily). Two months later the pulmonary lesions had almost entirely disappeared, and the patient was discharged. Eleven months after this he was seen again and was found to be completely cured.

The reporter, therefore, considers that this was a case of gummatous infiltration of the lungs with softening and formation of cavity.

None of the gentlemen whose opinions we have cited appear to have systematically utilized the bacillus test for the purposes of diagnosis. When this has been done, we may be able to get clearer conceptions of syphilitic pulmonary troubles. At present it is only certain that these affections, resembling in many respects tubercular phthisis, are greatly relieved or even positively cured by an antisyphilitic treatment.

THE PARASITIC ORIGIN OF CANCER.

The resemblance in many respects between cancer and tuberculosis has led of late to a renewed interest in the old question as to the infectiousness of cancer. Dr. A. Ledoux-Lebard, in the April number of the *Archives Générales de Médecine*, makes an elaborate plea in favor of the view that cancer is a parasitic disease. Under the

head of clinical and etiological considerations, he shows the analogies between cancer and known chronic infectious diseases, like tuberculosis. Under the head of pathological anatomy, he argues that cancer is a specific inflammation; while, under the head of experimental pathology, he cites the numerous experiments that have been made to determine the inoculability of cancer. The author admits that none of these are demonstrative, while most of them are absolute failures. The best cases are those of Goujon, who successfully inoculated cancerous nodules in a guinea-pig, using a fragment of an epithelial cancer from an animal of the same species. Klenke also is said to have successfully inoculated a horse with melanotic cancer. Dr. Lebard further cites facts which, as he thinks, prove that cancer is auto-inoculable. The natural history of actinomycosis is given as illustrating an infective parasitic disease, allied clinically to cancer, which is undoubtedly not inoculable.

Lebard has himself attempted inoculations of cancer without success. He has also tried, by various staining methods, to discover a characteristic micro-organism. In this, too, he failed, and at present the view that cancer is a parasitic disease continues to rest only upon analogical reasoning.

COMPULSORY MEMBERSHIP IN COUNTY MEDICAL SOCIETIES.

We call the attention of the physicians of this State to the report of the *comitia minora* of the New York County Medical Society as to the question of membership in county medical societies. This report, based upon opinion by the counsel of the Society, says that all practitioners of medicine are obliged by law to become members of a county medical society. No member can resign from such a society unless he at the same time ceases to practise medicine.

Membership may be exacted of every practitioner, under penalty of forfeiture of right to practise upon refusal. It appears from the report that this compulsory membership is due to a statute enacted in 1827, but still in force so far as this particular point is concerned.

A law which has been practically dead for fifty-eight years is not likely to exhibit much vitality now; and the report of the *comitia minora*, except so far as resignations are concerned, raises a matter which is chiefly of historical interest.

MEDICAL MARTYRDOM IN THE SOUTH.

A correspondent in Georgia writes us a curious story regarding the performances of Lulu Hurst, the magnetic girl, who exhibited herself in this city last summer. "This girl," he says, "is having large audiences in our section of the country, and a doctor or any one else dare not utter a word against her supposed 'new force' or *her tricks*. The medical profession here generally indorse her, and I am afraid that a medical friend and myself will be drummed out of the community if we do not get some indorsement of our views. Can you forward by mail or express, or any other way, any thing upon the subject—right away?"

Miss Hurst, he says, claims to be indorsed by the Charleston Medical Faculty, the Smithsonian Institution, and various other responsible bodies.

The methods of Lulu Hurst were thoroughly exposed while she was exhibiting in New York. Indeed, her performances were found to be too transparent and silly to deserve serious scientific scrutiny. We believe it is true that some of the quasi-scientific gentlemen of Washington, whose mental vision has become clouded by excessive measuring of bones, counting of fish scales, and classifying and pickling objects of natural history, have yielded obeisance to Miss Hurst.

But, however this may be, there is not a man of scientific training nor any reputable scientific journal that has given indorsement to the ingenious antics of the Georgia Wonder.

We trust that our correspondent and his friend will not have to suffer for their opinion's sake. Let them content themselves with knowing that they are in the right, and that all intelligent men of science are with them.

News of the Week.

On another page will be found an article by Dr. A. H. Smith on "Valvular Friction Sounds," to which we invite the attention of our readers. This is a new term in the nomenclature of heart affections, and if the conclusions arrived at by Dr. Smith are correct, it will take its place as indicating a very important physical sign.

Cancer-cures.—We are in receipt of a very considerable number of suggestions for the cure of cancer. One physician writes us that he treated a case of uterine cancer with chromic acid, ʒ j.; aquæ, ʒ j., applied with a camel's-hair pencil every other day. As yet there is no return of the disease. Another correspondent asks as to the value of the new Brazilian cancer-cure, "alveloz." Nothing has been established regarding it.

A New Medical Journal.—*Les Nouveaux Remèdes* is the title of a new bi-monthly journal edited by MM. G. Bardet and Delpech, published in Paris.

The Infectiousness and Bacillary Origin of Leprosy are claimed to be established by Drs. R. Melcher and P. Ortmann, of Königsberg. These gentlemen have succeeded in inoculating the disease in rabbits.

"In War Time," by Dr. S. Weir Mitchell, "Charley Kingston's Aunt," by Sir Henry Thompson, and a novel by Dr. Milner Fothergill are the latest contributions to professed fiction by medical men.

Homœopathy in Chicago.—Homœopathy flourishes in Chicago, and members of this ism, with few exceptions, thrive and wax fat. The two great schools of the system have recently graduated large classes. The total number of graduates from all schools of medicine in this city will probably exceed that of last or any preceding year. Hard times appears to increase the number of aspirants for medical honors.—*Philadelphia Medical Times.*

The Philadelphia Water-supply.—The Philadelphia County Medical Society has formally indorsed the statements of Col. Ludlow, regarding the water-supply of Philadelphia, as also the right and wisdom of his making certain disclosures regarding the insalubrious character of said supply.

The Late Professor Louis Elsberg.—The Medical Board of Charity Hospital, at its regular meeting held April 1, 1885, passed the following resolutions:

Whereas, Our late associate, Dr. Louis Elsberg, has been removed from us by death, therefore,

Resolved, That we, the Medical Board of Charity Hospital, express deep regret at the loss of our associate, whose interest in medical subjects and desire to advance medical science, and whose uniformly kind and courteous demeanor toward his patients as well as colleagues, won our esteem and admiration.

Resolved, That we express our appreciation of the services rendered to the hospital by the deceased, and our acknowledgment of his unabated zeal and fidelity in the performance of his hospital duties when failing health and bodily weakness required freedom from professional cares.

Resolved, That the death of Dr. Elsberg deprives this community of one of its most useful citizens, and the branch of medical science which he so successfully cultivated, of one of its most efficient promoters and highest authorities.

Resolved, That a copy of these resolutions be sent to the family of the deceased, and to the medical journals of this city.

J. Ferris Smith, M.D.,
William T. White, M.D.,
Committee.
Fessenden N. Otis, M.D., *President.*
J. Blake White, M.D., *Secretary.*

The Eleventh Annual Meeting of the American Neurological Association will be held in this city on Wednesday, June 17, 1885, and will continue three days.

Cholera and Railway Stations.—Cholera, in this country, being always due to importation, and its spread being, most commonly, by persons travelling from place to place, it follows that railway privies and water-closets are especially exposed to the danger of cholera-infection. In view of these facts, the Illinois State Board of Health has requested that all such places in connection with stations, freight-houses, shops, and round-houses be at once inspected and put in good sanitary condition. Responses have been received from nearly all the roads in the State, and one of the most important lines has already completed the work indicated along the entire extent of the road.

The Danger to Memphis.—The medical press and health authorities of Memphis, Tenn., claim that their city is in danger, because, owing to lack of capacity, several of the sewage mains have had to be tapped, and their contents discharged into the open bayou.

Money for Fighting Cholera.—The Appropriation Committee of the Illinois Legislature has decided to put in the General Appropriation bill a clause for $40,000 for the State Board of Health, as a contingent fund to be used in case of an outbreak of cholera.

Cholera in Spain.—Cholera has appeared to a considerable extent in several localities in Spain.

Ex-Surgeon-General Wales.—A writ of *habeas corpus*, applied for by Surgeon-General Wales, was this week refused by a civil court of the District of Columbia, in General Term. The basis of the refusal was the fact that the applicant was not in confinement or under physical restraint, but only under moral restraint, since he could leave the city if he chose to take the consequences. The court declined to consider the question of the jurisdiction of the court-martial, which is resisted by General Wales on the ground that he is charged with neglect of duty as a bureau officer, and not as an officer of the navy. The question thus raised will now be carried before the Supreme Court.

Death of Dr. Edward T. Ely.—We regret to announce the death, on April 12th, of Dr. Edward T. Ely, formerly of this city, and a well-known associate of Dr. D. B. St. J. Roosa. Dr. Ely was born in Rochester, N. Y., October 2, 1850, and was graduated from the Rochester University in 1871. He received the degree of M.D. from the College of Physicians and Surgeons in this city, in 1874. Dr. Ely, after graduating, was for some time resident physician in the Charity and Presbyterian Hospitals. He became associated with D. B. St. John Roosa in 1875. He made a number of important contributions to ophthalmology and otology. He married in 1882, and spent some time in Europe. His widow and an infant daughter survive him.

Licensing Midwives.—The action of the Buffalo Medical and Surgical Association in appointing a committee to draft a bill for presentation to the Legislature, providing for the licensing of midwives, after due examination by a board of legally qualified physicians, has been supplemented by that of the Medical Society of the County of Erie. This latter society has indorsed the action of the former, adopted the draft of the bill as presented by the committee, and referred it to the Legislature with the recommendation that it be passed.

Dr. Stanford E. Chaille has been appointed by the President to fill the vacancy in the National Board of Health caused by the death of Dr. Bemiss.

The State Medical Society of Arkansas will meet at Little Rock on April 22d.

The Medical Society of the State of Tennessee held its annual meeting at Nashville on April 14th, 15th, and 16th.

The Medical Association of Georgia met at Savannah on April 15th.

The Medical Society of the State of Alabama held its annual session at Greenville, beginning April 14th.

The California State Medical Society met at San Francisco, April 14th, 15th, and 16th.

The Mississippi State Medical Society held its annual session at Greenville during the past week.

The Illinois State Medical Society meets this year at Springfield on May 19th.

For Services During the Cholera Epidemic.—The French Government has given a number of gold, silver, and bronze medals, as a recompense for services rendered during the cholera epidemic. Dr. Ballivet received one of the gold medals; most of the other recipients were priests or sisters.

New York Infant Asylum.—The Board of the New York Infant Asylum has recently appointed by competitive examination Elizabeth Burr-Thelberg, M.D., to the vacancy at the Mount Vernon branch of the institution.

The American Journal of Neurology and Psychiatry has been discontinued.

Dr. Edward T. Reichert has been appointed Lecturer on Physiology in the University of Pennsylvania, to fill the place of Dr. Harrison Allen, resigned.

Medical Colleges.—Jefferson Medical College, at its annual commencement, April 2d, graduated a class of 176. The Cincinnati College of Medicine and Surgery graduated 25 at its annual commencement; Miami College, 27; Ohio Medical College, 58; Columbus Medical College, 18; Sterling Medical College, 30; the Chicago College of Physicians and Surgeons, 60.

If Dr. Gaillard were still alive, the next issue of his journal would probably call attention to the following sentence from page 321 of the *Journal of the American Medical Association:* "The frightened subject pulled on his penis and manipulated it in such a manner as to cause its total passage into the bladder." We hasten to relieve our readers by stating that the context shows it was a foreign body, and not the penis, that thus passed into the bladder.—*Columbus Medical Journal.*

Sir James Paget was recently elected corresponding member of the Académie des Sciences, defeating Sir Joseph Lister, by a vote of 38 to 2.

In Memory of Dr. James L. Little.—At a meeting of the students of the medical class of the University of Vermont, held April 6th, the following resolutions were adopted:

Whereas, It has pleased Almighty God to remove from us our beloved Professor, Dr. James L. Little, and whereas the present class of the Medical Department of the University of Vermont desire to express their feeling of regard and respect for their late instructor, and sorrow for his death; therefore be it

Resolved, That we tender our heartfelt sympathy to his afflicted family.

Resolved, That in his death the medical fraternity has lost one of its most zealous workers, the student a valuable instructor and friend, and the world a noble Christian and benefactor.

Resolved, That a fitting emblem of mourning be placed in the lecture-room of the College, to remain during the remainder of the session.

Resolved, That a copy of these resolutions be forwarded to the afflicted family, the medical faculty of this College, The Medical Record of New York City, and the local press of this city.

M. E. Carmer,
E. M. King,
Emil Bories.
Committee of the Class.

The Medical Association of the District of Columbia elected officers for the ensuing year, on the 7th inst., as follows: Dr. D. C. Patterson, President; Drs. A. F. A. King and J. O. Stanton, Vice-Presidents; Dr. Lachlan Tyler, Secretary; Dr. S. S. Adams, Treasurer.

The Prophylaxis of Erysipelas is the subject at present occupying the attention of the Paris Académie de Médecine. M. Guérin is sure that erysipelas can be prevented by the use of his antiseptic pads. M. Polaillon expresses equal confidence in the liberal use of five per cent. carbolic acid solutions. M. Panas advocates the bichloride of mercury solutions as least dangerous and irritative.

Reviews and Notices.

Manual of Diseases of the Ear. By Thomas Barr, M.D. Pp. 529. Glasgow: James Maclehose & Sons. 1884.

The author has collected an interesting mass of material, rather giving such views from the literature as accord with his own than presenting the subject broadly, and he has been inspired from a German rather than an English point of view. We regret that space will only permit a brief review of the work. On pages 141-147 a very good description of the operation of perforating the mastoid process is given. Quoting the special advocate of this operation, Schwartze, the mortality is stated to be about two per cent.; the subsequent treatment extends from one month to two years, and seventy-five per cent., it is alleged, ultimately recover. The author himself favoring this operation, we have diligently sought for some reliable indications that would warrant the procedure, but it could only be learned that he believes that conclusive evidence of the existence in the mastoid cells of retained pus or secretion rarely exists; that they may be present, with necrosed bone, without subjective or objective symptoms; that inflammatory phenomena, on the other hand, may exist, and yet no purulent accumulation be found. He says that in chronic purulent inflammation of the middle ear, where suspicion of extension to intracranial parts arises and pain in the mastoid exists, without redness or swelling, the results of an operation are uncertain, since the disease may have already extended to vital parts. With no evidence of mastoid inflammation, tenderness on pressure or percussion, and pretty clear evidence that the dura mater or venous channels have become involved, little benefit is to be expected from an operation. The object of the operation is, it is said, to make an opening through the shell of bone forming the outer wall of the antrum mastoideum, in order to secure free drainage from the antrum, tympanic cavity, and external auditory canal, as well as for thorough cleansing. Considering the danger to life attending this operation, the actual harm arising from the wounding of the parts, and the comparatively meagre results claimed to have been attained, it is difficult to accept the assertion of the author, that "in certain cases this operation is one which, in importance, may rank with tracheotomy in diphtheria or with the operation for the relief of strangulated hernia, as an operation for the saving of life." It seems to be true that much unnecessary suffering has been caused to patients by futile operations on the ear, done under the plea of improving drainage and saving life in alarming cases, where it has been thought that energetic measures were alone commensurable with the danger of the situation.

The author queries whether, in obstinate suppurative inflammation of the middle ear, it is not good practice to cut down through healthy tissue and remove a small wedge of bone, one-fourth of an inch in extent, without opening the mastoid cells. Otologists, fortunately, are not unanimous in recommending this pretentious and would-be-impressive procedure, failing to see how it could expedite a cure.

The book possesses literary merit and is a valuable summary of much of the writing done by otologists during

the past ten or fifteen years, and notwithstanding the author's apology, credit to authorities should have been more frequently accorded. The arrangement of the subject matter and the classification of aural diseases is excellent. The cuts are good, the type plain, and there is a commendable absence of the tedious relation of cases.

A Manual of Dissection of the Human Body. By Luther Holden, late President of the Royal College of Surgeons of England; Consulting Surgeon to St. Bartholomew's and the Foundling Hospitals. Fifth Edition. Edited by John Langton, Surgeon to, and Lecturer on Anatomy at, St. Bartholomew's Hospital, etc. 8vo, pp. 886. P. Blakiston, Son & Co. 1885.

No student of anatomy can take up this book without being pleased and instructed. It is arranged differently from any other work of its kind. Its diagrams are original, striking, and suggestive, giving more at a glance than pages of text description. All this is known to those who are already acquainted with this admirable work, but it is simple justice to its value as a work for careful study and reference that these points be emphasized to such as are commencing their studies. The text matches the illustrations in directness of practical application and clearness of detail. The last edition of this work, as a whole, bears evidence of careful revision, while very many valuable additions have been made in the anatomy of the nervous system and the organs of special sense.

Transactions of the Academy of Medicine in Ireland. Vol. II. Edited by William Thomson, M.A., F.R.C.S. 8vo, pp. 504. Dublin: Fannin & Co. 1884.

This handsomely printed and beautifully illustrated volume is the second of a series of the Transactions of the Academy of Medicine of Ireland, and contains a variety of interesting and unique cases in the different departments of medicine, surgery, and obstetrics. The editor has shown rare judgment in his selections, and the short and numerous papers cover a range of rarity and practical applicability such as is seldom comprised in similar volumes. The Academy is evidently a working and progressive body, and does itself and the British profession credit in allowing its lights to shine thus.

Transactions of the College of Physicians of Philadelphia. Vol. VII. 8vo. P. Blakiston & Son. 1884.

This volume fully maintains the reputation of former ones, and contains many notable contributions from many of the distinguished members of the college. Without intending to make any invidious distinction we would predict the widest reading for the papers on Enteric Fever, by Dr. J. C. Wilson; on Nasal Catarrh of Children, and also on the Method of Recording the Motions of the Soft Palate, by Dr. Harrison Allen; Cholecystotomy, by Drs. Musser and Keen; and the admirable and scholarly memoir of Dr. S. D. Gross, by Dr. I. Minis Hays.

Our Bodies; or, How We Live. An Elementary Textbook of Physiology and Hygiene. By Albert F. Blaisdell, M.D. 12mo, pp. 262. Boston: Lee & Shepard. 1885.

This is a physiology for young folks, and will serve its purpose exceedingly well.

Bodily Deformities and their Treatment. A Handbook of Practical Orthopædics. By Henry Albert Reeves, F.R.C.S.E., Surgeon to the Royal Orthopædic Hospital, London, etc. 12mo, pp. 460. Philadelphia: P. Blakiston, Son & Co.

This little volume is presented to the profession by a general surgeon interested in this special domain of surgery. It confines itself to the pathology and treatment of deformities of the limbs and analyzes in a very impartial and straightforward manner the methods, mechanical and operative, which are advocated by different authorities. The particularly valuable part of the work is that referring to osteotomy of the different anchyloses, particularly that of the knee. Although the author leans with partiality toward his own operation, he is conservative and just regarding the merits of others. The chapters on spring-fingers and paralytic dislocations contain much novel and interesting material. Although the work is well printed the wood-cuts are abominable.

One Hundred Years of Publishing, 1785–1885. Pp. 20. Philadelphia: Lea Brothers & Co. 1885.

In our youthful republic, with its varied industries and short avenues to commercial prosperity, the transmission of a business from father to son down through four generations is of very rare occurrence. Yet it has happened in the history of the publishing house above named. The autobiography is gracefully told in the neat little volume just issued and bearing the above title. The founder of the house, Matthew Casey, landed in Philadelphia in 1784. Though scarcely yet entered upon young manhood, he had already passed through many stirring scenes in his native Hibernia. His energy found scope in journalistic and publishing enterprises, which are perpetuated in the house of to-day. The pride of the latter is certainly pardonable, as its members can look back upon a record reaching nearly to the close of the Revolution; particularly so when this record has never been tarnished by the least taint of commercial dishonor. In the words of its well-told tale, "It has ever entertained a high sense of respect for its own imprint, and has felt a just pride in the belief that its name on a title-page was in some sort an indication of the worthiness of the volume in which it appeared."

Révue Bibliographique Universelle des Sciences Médicales.

This is a comparatively new monthly periodical devoted to recording the progress of medical science. An annual alphabetical index is also published. The editor in-chief is Dr. Eugene Martel, No. 6 Place Saint-Michael, Paris.

Proceedings of the Philadelphia County Medical Society. Vol. VI. September, 1883, to June, 1884. Philadelphia, 1884. Edited by the Publication Committee.

A well-printed volume containing many valuable papers.

Medical Journalism in Cuba.—The *Enciclopedia*, a monthly review recently established in Havana, gives in its prospectus a brief history of medical journalism in that island. The first in the field was *El Reportorio Médico*, established in 1840 by Dr. N. J. Gutierrez, and followed three years later by *El Boletin Científico*. From that date to 1854 six other journals saw the light, but most of them died in infancy. During the following decade three more journals appeared on the scene, the *Revista Médica de Cuba*, *El Estímulo*, which in spite of its name received but little encouragement, and *La Emulacion*, which emulated its predecessor in the brevity of its existence. In 1864 the publication was begun of the *Anales de la Real Academia* and is still maintained. The next decade also produced three short-lived papers, and in May, 1875, appeared the *Crónica Médico-Quirúrgica* of Havana, an excellent periodical, which reflects credit upon the medical profession of Cuba. The ten years which have since elapsed have been very prolific, having produced no less than fifteen periodicals devoted to medicine, dentistry, pharmacy and public health, several of which are still published regularly. One would suppose that there would be considerable jealousy of each other among so many publications in a country the size of Cuba, but that a spirit of generous rivalry animates some at least is evidenced by the fact that this prospectus, from which we derive our information, is reprinted in the *Eco Científico de la Villas*, with the best wishes of the editor, Dr. Reyes, for his young contemporary.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 25, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. W. M. CARPENTER presented, in behalf of a candidate, a specimen of *congenital umbilical hernia.*

DR. JAMES B. HUNTER presented, in behalf of a candidate, a specimen of *cyst of the broad ligament.*

DR. H. J. BOLDT presented the

TRACHEA AND LUNGS (DIPHTHERITIC CROUP)

removed from the body of a child, which died of diphtheria sixty-three hours after tracheotomy. The specimens presented the characteristic features which confirmed some of the views recently expressed at previous meetings of the Society, namely, that, as a rule, the lungs of patients who die from asphyxia are more or less anæmic and not congested.

OVARIAN TUMOR—TWISTING OF THE PEDICLE—PERITONITIS—OPERATION—RECOVERY.

DR. JAMES B. HUNTER presented a specimen which had some peculiarities worthy of notice. The patient first came for examination about the middle of last December, when it was doubtful whether the abdominal enlargement was due to a tumor or not. Early in January, however, the examination was repeated, and it was then evident that she had an ovarian tumor, but as there was no pain the patient decided to wait awhile before having an operation performed. A little later in January she reported rather suddenly that she had severe pain, and she was transferred to the hospital at once, with a temperature of 100.5° F., and evidence of beginning peritonitis. After entering the hospital, which was on February 25th, her temperature continued day and night at 101° F., the pulse from 130 to 140. Dr. Hunter decided to operate as soon as possible, and on February 27th performed the usual operation, when he found a cyst covered with large veins; the least prick of the tumor was followed by copious hemorrhage. There were a few recent adhesions. The pedicle was twisted upon itself five times, which produced congestion and strangulation of the tumor. Hemorrhage had occurred between the walls of the tumor to such an extent that clots of blood in places filled the entire interspace, and the fluid contents of the enlarged cyst were partly bloody. After the operation the patient's temperature was 101.5° F., the pulse 140. Ten hours after the operation the temperature was 98° F., the pulse below 100, and the patient from that date progressed favorably to a good recovery.

Dr. Hunter had seen another case in which sudden twisting of the tumor gave rise to alarming symptoms, and he thought that if the operation had been postponed in this case two or three days longer the prognosis would have been very bad.

DR. T. MITCHELL PRUDDEN presented a specimen of

CYST-ADENOMA OF THE OVARY,

for which he was indebted to Dr. Edward J. Ill, of Newark, N. J., by whom it was removed. The tumor was removed from a patient, twenty-eight years of age, who noticed the growth since the birth of her last child seventeen months ago.

At the operation the tumor was found to have originated in the right ovary. The abdominal cavity contained about three pounds of a thick gelatinous substance. (The tumor had not been aspirated.) The peritoneum itself was covered with a thick layer of lymph.

The woman died on the fifth day after the operation, apparently from septicæmia, which it was conjectured might have been due to the breaking down of the fibrin which was in the peritoneal cavity before the operation, as no lesions were observed other than those mentioned and those connected with the operation.

"The tumor, about ten inches in diameter, is a typical *cyst-adenoma* of the *multilocular form*, and the gelatinous ropy fluid which the cysts contain show under the microscope the various cellular elements so often observed in these fluids, cylindrical and flattened epithelium, beaker cells, fatty pus cells, and fatty epithelium, and the so-called 'compound granular corpuscles.'

"At one side of the tumor there is a more solid mass of tissue, about the size of the fist, considerably resembling in its general appearance some of the less vascular malignant tumors. This proves, however, on microscopical examination to be simply an adenomatous mass of tissue in which the cystic transformation has made but little progress. A section from this portion of the tumor is shown under the microscope, in which the enormous papillary outgrowth into the closed cavities is well exhibited. The microscopical specimen also shows very well the various forms of cells as they lie in the still unruptured cysts.

"The case is presented partly because of the complication of the rupture of one of the cysts before the operation, and partly because of the rather unusually typical appearances of the solid parts of the growth as seen in microscopical section."

DR. HUNTER asked if the peritoneum was involved.

DR. PRUDDEN replied that there was no record of anything excepting the inflammatory action attacking the peritoneum; there was no colloid change.

DR. HUNTER remarked that he removed a tumor Monday last, almost the counterpart of the specimen presented by Dr. Prudden. The patient was fifty-one years of age, and the peritoneum was in a condition of colloid degeneration on one side. The tumor itself presented evidences of being carcinomatous.

PECULIAR FORM OF HEMATOIDIN CRYSTALS.

DR. L. WALDSTEIN presented a microscopical slide from a tumor removed from the testicle, which exhibited peculiar hematoidin crystals of which he had been unable to find any description, nor did he remember to have seen this form of crystal before. The usual form of hematoidin crystals is the rhombic in different stages of development. In the present instance the crystals were in the form of small rods collected in the shape of asterisks and in the form of sheaves. There was no evidence of hemorrhage in the tumor. These crystals were found in different parts of the tumor, which was of about the size of a hen's egg. He would not venture to explain why they took this form, but simply called attention to the fact that the size of crystals is said to depend upon the slowness of crystallization and the clearness of the mother liquid. He supposed that there were small hemorrhages from capillary vessels, of which there was no vestige left except these masses of hematoidin.

DR. JANEWAY said he had seen similar crystals in the urine, occurring very rarely, and that Eichhorst, in his work on "Physical Diagnosis," had illustrated this form of hematoidin crystal.

DR. VAN SANTVOORD presented a specimen of

TUBERCULAR LARYNGITIS,

removed from the body of a male, thirty-five years of age. The specimen presented no peculiarities except that it was fresh, and illustrated the lesion very well. There was nothing peculiar concerning the clinical history. The larynx showed the superficial left half of the epiglottis more or less ulcerated, with small ulcerations in the navicular fossa, and a slight amount of ulceration over the arytenoids. There was extensive disease of the lungs, consisting of fibrous induration of the upper lobes with small cavities, and somewhat extensive cheesy foci in different parts of the lungs. There were tubercles in the liver, and also tubercular ulceration of the intestine.

DR. BOLDT asked if there was any pathological lesion in the lungs previous to the laryngeal disease.

DR. VAN SANTVOORD answered that a month before

death the lungs were examined and found in an advanced stage of disease. He thought it probable from what history he could obtain, the patient being a hospital patient, that the lungs were primarily diseased, and that the ulcerative laryngitis was secondary.

PSOAS AND ILIAC ABSCESS OPENING INTO THE DUODENUM.

DR. JANEWAY presented a specimen removed from the body of a woman forty-five years of age, who was admitted to Bellevue Hospital November 29, 1884, with a history of having been sick five weeks with pain in the right lumbar region, down the right thigh, coming on apparently suddenly, followed by flexion of the thigh upon the pelvis and of the leg upon the thigh. These symptoms continued more or less up to the time of death. There was but little fever. The temperature toward the close of life being as low as 95° F. No distinct swelling was detected in the groin, although there was a sensation of deep-seated infiltration, which was explored with a hypodermic needle twice without obtaining pus.

At the autopsy there was found a small ulcer opening into the duodenum just as the descending turns into the transverse portion of the gut. For a time there was diarrhœa during life, but no pus was detected in the stools on inspection with the naked eye. A deep abscess with thick walls was found in the iliac region. There was thrombosis of both iliac arteries.

Dr. Janeway also presented a specimen of

PERFORATING ULCER OF THE ŒSOPHAGUS,

with such lesions as made it quite certain that it was ante- and not post-mortem perforation. The patient had infantile paralysis at one year of age, subsequently aphthous sore mouth following measles, with bronchitis and afterward dysentery. It died comparatively suddenly. At autopsy there was also evidence of recent bronchitis and pleurisy, but there was no history of elevation of temperature. About one inch above the cardiac extremity of the œsophagus on the left lateral wall, inclining toward the anterior wall, was a round ulcer about one-half an inch in diameter, perforating the mucous membrane, and making a smaller opening through the connective tissue and muscular coats. It presented exactly the gross appearance of a round perforating ulcer of the stomach, sometimes called "peptic ulcer." Exactly what was in the centre of this opening before the ulceration took place he was unable to say, but there was no disease of the arteries.

THE PRESIDENT remarked that in all the cases of rupture of the œsophagus on record the opening occurred in this region.

DR. JANEWAY also presented a specimen of

TRACHEAL STENOSIS,

as a result of cheesy enlargement of a gland pressing upon the right side of the trachea, and finally ulcerating into the trachea and producing complete stenosis. The child was two years and a half of age, and died suddenly. There was fibrous induration of the right upper lobe, due to stenosis of the right bronchial tube from surrounding lymphatic glands. A similar case was reported at the London Pathological Society about a month ago. He was indebted to Dr. Jenkins, Deputy Coroner, for the specimen.

DR. AMIDON said that recently he saw, in consultation, a child, about seven years of age, who was suffering from painful paraplegia, and both legs were in the position assumed with psoas abscess, with considerable tumor in the iliac region, which disappeared after the administration of an enema. The stools were not examined. When he saw the patient the temperature was hectic in character, and there was still a painful paraplegic affection, with considerable atrophy, and tendency toward degenerative reaction of the muscles. The tumor in the iliac region had disappeared, and the diagnosis had been made against Pott's disease. On making a careful examination, however, he discovered a knuckle at the junction of the dorsal and lumbar regions of the spine which was irreducible, and he suggested that the tumor in the iliac region was a cold abscess originally, which had ruptured into the rectum and had been discharged, and that the case was originally one of acute Pott's disease.

DR. JANEWAY said that there was no Pott's disease in his case. He had seen a number of cases of psoas abscess independent of tubercular or other trouble affecting the spine. He also remarked that one source of error, to be regarded in examining the stools for pus, was that, when bismuth had been administered, the stools were so blackened that it was difficult to detect pus by examination with the naked eye.

THE PRESIDENT asked Dr. Janeway if he had seen many specimens of ulcer of the stomach from the action of peptic juice.

DR. JANEWAY replied that he had seen a number of such cases.

THE PRESIDENT referred to one case in which death was produced by a gunshot wound, and at the autopsy, at which Dr. Janeway was present, an ulcer was found in the stomach fully an inch in diameter, which was supposed to be a peptic ulcer.

DR. PRUDDEN asked if the tissue just behind the ulcer in the œsophagus had been examined microscopically.

DR. JANEWAY replied that he had examined it slightly, and all that was shown was fatty, broken-down tissue.

DR. AMIDON asked what the immediate cause of death was in the case of stenosis of the trachea.

DR. JANEWAY replied that death was produced by asphyxia from complete obstruction of the trachea, produced by the cheesy gland.

PERITYPHLITIC ABSCESS—CASEOUS FOCUS IN ONE LUNG, WITH MILIARY TUBERCLES IN THE CENTRE.

DR. PEABODY presented the right iliac muscle, the cæcum and the vermiform appendix, removed from the body of a child twelve years of age, who was brought into the New York Hospital about a week ago with the following history: The girl was in good health up to ten days before admission, at which time she was taken with pain in the belly, followed by obstinate diarrhœa, which continued up to the time of admission, but without dysenteric symptoms. Her temperature ranged from 103° to 105° F. on the first day of hospital life, and besides that the pulse was very frequent and irregular. There was marked distention of the entire abdomen, with pain and tenderness in the right iliac region, following the course of the ascending and transverse colon. There was dulness also over the region of the cæcum and ascending and transverse colon, owing to frequent chills, to pain and tenderness in the right iliac region, and to copious fæcal stools, which occurred after giving a free purge, it seemed that suppuration was going on, but had not invaded the peritoneal cavity, and was probably in the region of the cæcum. Exploratory puncture was performed by a surgeon, and a long exploring needle was introduced and moved about pretty freely, but no pus was obtained. It was then suggested that, as the child's condition was very grave, there was no hope except in laparotomy, but the poor condition of the patient prevented the operation.

The autopsy revealed, beneath the cæcum and enclosing the vermiform appendix, an abscess cavity, entirely cut off from the peritoneum, into which he could insert the first two joints of his forefinger, and which was full of pus. The vermiform appendix was covered with lymph, was very soft and friable, but no ulceration had taken place into the interior. The interior of the vermiform appendix contained a mass of hard fæcal matter, three-fourths of an inch long, and as large as the prong of an ordinary dinner fork.

The exploring needle had penetrated the right kidney, also the liver, and there were large blood-clots in the immediate neighborhood of these organs.

There was in the right lung a caseous mass, as large as the tip of his little finger, and in the middle of it a group of miliary tubercles without other pulmonary changes. There were a number of caseous foci in the liver.

The cause of death was exhaustion from prolonged fever and constitutional disturbance. He had examined the abscess cavity and had not found evidence of tubercles elsewhere.

ATHEROMATOUS DEGENERATION OF THE CORONARY ARTERIES—FIBROUS INTERSTITIAL MYOCARDITIS.

Dr. Peabody presented the heart removed from the body of a man sixty years of age, who had led a very active life of excitement and dissipation, and who died very suddenly while in apparent health.

The autopsy showed dilated left ventricle, with atheroma of the aorta, thickening of the attached borders of the aortic cusps, with extensive atheromatous disease of both coronary arteries, which had thickened their walls and narrowed their calibre, also fibrous interstitial myocarditis. There was also found chronic diffuse nephritis.

Dr. Janeway remarked that considerable tumors sometimes formed from simply tympanitic distention of the cæcum, probably preceded by typhlitis. A difficult point in diagnosis was that when perforation of the vermiform appendix existed gaseous distention of the cæcum sometimes occurred from decomposition of the pus below.

The President said that he once operated for Dr. Loomis in a case the chief interest of which centred in the fact that there was an enormous quantity of pus in the region of the cæcum which had not been diagnosticated.

Dr. Janeway referred to the case of a woman who was taken with vomiting, and died suddenly. At the autopsy there was found endarteritis surrounding both coronary arteries, and narrowing one so that it was not larger than a knitting-needle, and the other was about twice that size. There was atheromatous degeneration of the aorta also. Probably death would not have occurred merely from the vomiting except for the condition of things in the aorta and coronary arteries.

Dr. Prudden asked Dr. Peabody if he thought that spasmodic closure had anything to do with occluding the coronary arteries in his case.

Dr. Peabody could hardly imagine that this occurred, because the walls of the arteries were so unyielding. It had occurred to him, also, to find in another case of sudden death the same lesion in the muscular wall of the heart to which he had referred.

Dr. Van Santvoord thought that in connection with this subject the experiments of Cohnheim, performed with reference to the cardiac circulation, were important. He found that, by occluding the coronary arteries, when a certain amount of anæmia was reached, the transition from the moderately well-working ventricle to paralysis was very sudden; the heart, instead of losing its contractile power, contracted normally up to the production of a certain degree of anæmia, when sudden paralysis occurred.

The President said that Cohnheim's experiments also proved that thrombosis of the terminal branches of the coronary artery would produce death in a similar way.

Dr. Janeway referred to a case, that of a gentleman who died suddenly at midnight, with symptoms of angina, and who had had only one other attack, which occurred about three weeks ago. At the autopsy there were found complete thrombosis of one coronary artery and obliteration of about two-thirds of the other. The heart-wall looked very well. He was surprised to find complete occlusion of one coronary artery and about two-thirds of the calibre of the other, and it seemed to him that the occlusion of one was of later date than that of the other.

Dr. Waldstein recalled a case which he saw about three months ago, that of a gentleman who had suffered from angina pectoris for several years. At the autopsy he was surprised to find the heart-muscle changed very extensively, myocarditis in patches, enormous foci of infarction; both coronary arteries were atheromatous, and, on microscopical examination of the myocardium, all the arteries detected in the field showed signs of endarteritis. Around the arteries the muscular fibres showed various degrees of fibrous myocarditis.

This case was interesting, in contradistinction to the one presented by Dr. Peabody, in the fact that this gentleman lived six or seven years, suffered from occasional attacks of angina pectoris, and his death was not sudden. Dr. Waldstein attached more importance to the myocarditis in the heart presented, and also in his own case, than to the atheroma of the coronary arteries.

Dr. Peabody had supposed that interference with the nutrition of the heart was the primary cause of degeneration of the muscular wall of the heart, and that the degeneration of the muscular wall was the cause of sudden death, and that degeneration of the arteries was only secondarily the cause of death.

Dr. Prudden said that in estimating the value of Cohnheim's experiments, it should be borne in mind that the occlusion of the artery was produced in a healthy heart, and was acute occlusion, and that in a considerable number of cases both these conditions must be taken into account, namely, a weakened myocardium and possibly a sudden closure of diseased arteries.

Dr. Janeway remarked that clinically these cases must be discriminated.

Dr. Peabody asked Dr. Janeway if he thought he could be sure of determining the good condition of the muscular tissue of the heart by the naked-eye examination.

Dr. Janeway replied that he could not.

Dr. Peabody stated that he had seen very many cases in which the muscular tissue of the heart was apparently normal, but on microscopical examination extensive change was revealed.

The President suggested that the nutrition of the heart might possibly be affected by disease of the blood-vessels which supplied the central ganglia.

The Society then went into executive session.

PRACTITIONERS' SOCIETY OF THE CITY OF NEW YORK.

Stated Meeting, April 3, 1885.

A. Brayton Ball, M.D., President, in the Chair.

Dr. C. L. Dana reported a case of

BILATERAL CLONIC SPASM OF THE PLATYSMA MYOID MUSCLES

in a man twenty-seven years of age, and by occupation a longshoreman. He had been a healthy man previous to this disease, but had indulged in masturbation to a very great excess, which he had ceased six months before Dr. Dana saw him, when the patient complained of general nervous prostration, weakness, and inability to work, but the main symptoms were clonic spasms affecting both platysma muscles, showing themselves like the jerking and shaking of the skin of a horse when annoyed by flies. These spasms occurred especially when the patient was nervous and excited, and the muscles of the face were affected occasionally on both sides, and occasionally some of the pectoral muscles exhibited the same disorder. In other respects the condition of the patient was very good. On testing him there was found no sensory or other disturbance, and the muscular spasms were not painful. At first sedatives were used, such as bromides with tonics, but without any apparent benefit. They were continued for two or three weeks, when the patient was put upon large and increasing doses of arsenic, and in the course of about six weeks he got well. The entire course of the disease was about three months. Dr. Dana had been unable to find any record of a case of this kind. Cases were on record in which one of the branches of the seventh nerve had been affected more than any

other by such spasms, but clonic spasms of the lower branch of this nerve, so far as he was aware, had not been recorded. He regarded this condition as similar to the convulsive tic of the face, writer's cramp, etc., rather than of a choreic kind.

The points of interest in the case were, first, the cause, prolonged masturbation; second, the fact that it was cured.

Dr. Samuel Sexton related a case of

DESQUAMATIVE INFLAMMATION OF THE EXTERNAL AUDITORY CANAL, ASSOCIATED WITH ACUTE CATARRHAL INFLAMMATION OF THE MIDDLE EAR, AND THE FORMATION OF AN EXTENSIVE SANGUINOLENT TUMOR IN THE CANAL.

The patient was a porter, aged sixty-four, who presented himself recently at the New York Eye and Ear Infirmary for treatment. The notes of the case were taken by my assistant, Dr. Bartlett. The external auditory canals were very large, and protruding from the left meatus was a purplish sacculated tumor with a decidedly corrugated surface. On examination it was found that nearly the whole dermic lining of the external auditory canal was detached as far outwardly as the cartilaginous portion, the denudation including the posterior and superior segment of the drumhead, the latter being limited anteriorly by its attachment to the handle of the malleus. There had been a sudden hemorrhage into the sac thus formed, from the vessels constituting the plexus coming from the canal down along the handle of the malleus. That the sac was large enough to protrude from the meatus externus was owing to the large area laid bare along the superior wall of the canal, and down over the drumhead. A probe could be passed freely under the sac down into the cul-de-sac, but not farther along the superior wall than to the beginning of the osseous portion. The dermic layer on the posterior inferior wall was found to be loosened and easily peeled off. The sac on being punctured partially collapsed, giving vent to bloody serum.

The patient gave the following history: For some time he had had a severe catarrhal attack affecting the upper air tract, and three days before coming his left ear was invaded. The attack came on while he was in bed, with pain and tinnitus; it was so sudden as to wake him from sleep, and he looked around to see where the noise came from. He observed that there was some bloody discharge. He experienced autophonia which increased the distress. He could hear only shouting in the affected ear. A few days subsequently to his coming the sac had not refilled, but had a red fleshy appearance; the exact point to which this mass was attached could not be determined. The canal was found filled with bloody serum, which was removed and the parts dressed with powdered boracic acid. Four days later the mass of skin was much more shrunken, but bled slightly on manipulation; *it was now found to be attached to the handle of the malleus from the short process to the umbo*, and was removed with the snare, the base being afterward trimmed with cutting forceps. The parts soon afterward cleared up and hearing improved, no perforation ever having taken place. A dark cicatrix soon showed itself, anterior to the malleus handle and parallel to it, which gradually moved over the anterior segment of the membrana tympani toward the anterior wall of the canal. Hearing had continued to improve when the patient was last seen, but the middle-ear catarrh proved rather intractable to treatment. It was believed by Dr. Sexton that this case afforded an explanation to the phenomena of hemorrhage sometimes reported in connection with catarrhal inflammation of the middle ear; he had observed many such cases where a slight sanguineous tumor had formed in this way. Dr. Frank Ferguson, who kindly examined the specimen removed by the snare, regarded it simply as a blood-clot. There was no newly formed tissue.

PERITYPHLITIS.

The President, Dr. Ball, reported a case of perityphlitis occurring in a gentleman about fifty-eight years of age, who had always been in good health, but who was attacked on January 20th, while down town, with a pain in the stomach, which he regarded as simple colic, but severe enough to make him desire relief, and he went to a neighboring apothecary, who gave him some simple mixture, the nature of which he did not know. But the pain gradually increased, and on reaching home he sent for Dr. Ball, who was absent from the city, and Dr. Hackley saw the patient, who appeared to be suffering from intestinal colic. In the right groin was a softish protuberance, which had very much the appearance of a femoral hernia, but it had been there for two years, and had remained unchanged. This mass was irreducible, and was not at all sensitive to pressure. There was no special pain on pressure anywhere over the abdomen, but there had been one attack of vomiting. Dr. Hackley was inclined to think that the attack had nothing to do with the apparent hernia, and gave the patient a hypodermic injection of morphine.

On the following morning Dr. Ball found him decidedly more comfortable, there had been no more vomiting and no more morphine had been required, and all that the patient complained of was a sense of discomfort. It was evident, however, that the mischief was not entirely relieved. Being unable to divest himself of the idea that this apparent hernia might have something to do with the attack, Dr. Ball called Dr. H. B. Sands in consultation, who made a very careful examination and reached the conclusion that the man had apparently a femoral hernia, but was unable to see any connection between it and the pain in the right groin. There was no fever. The condition of the patient was such as seemed not to require the administration of medicine, and the result of the consultation was, therefore, a rather expectant plan of treatment. In the evening of the same day there was no apparent change, although the patient still suffered somewhat, and Dr. Ball gave him morphine. On Friday morning the patient was very much better, but for all that there remained a feeling as if there was something wrong in the abdomen, yet nothing amounting to actual pain. He told his patient to be careful for a few days, and if any new developments occurred to let him know at once, as the entire absence of fever and no return of the vomiting, and with the pulse entirely normal from Wednesday noon to that date, warranted him in not continuing his visits regularly.

He was called on the following Monday evening, and found that the patient had been down town that day; that he had felt very well Saturday and Sunday. While down town he began to have more trouble, with return of pain, and when Dr. Ball saw him in the evening there had been one attack of vomiting. At that time there was no fever, no increased frequency of the pulse, and nothing abnormal to be felt in the abdominal cavity except a slight increased resistance in the right iliac fossa, but without any special tenderness.

He put his patient on the opium treatment, however, and Dr. Sands saw him again in consultation on the following morning, when he was suffering rather more pain, and there was some resistance on pressure over the right iliac region, and there could be felt a mass beginning at Poupart's ligament and extending upward for between two and three inches, and situated midway between the anterior superior spinous process of the ilium and the median line, not located where we would expect to find a perityphlitic tumor. The question was, what was this swelling? It was situated directly above the apparent hernia, and yet not in the location ordinarily occupied by perityphlitis. There was no evidence of obstruction of the bowels, as they moved daily. The case was very puzzling. From that time on the patient became steadily worse, the mass increased in size, vomiting developed on Wednesday, of fluid which had more or less stercora-

ceous appearance, but no stercoraceous odor, the irritability of the stomach continued during the remainder of the patient's life, and there was no special change for two or three days except gradually for the worse. During all this time there was no fever whatever, the pulse ranging from seventy to eighty until Thursday, and from Tuesday to Thursday there was no movement of the bowels, which could be readily accounted for by the fact that the patient was taking considerable opium. At about one o'clock on Friday morning the patient was taken with very severe pain in the abdomen, vomited more frequently, and when Dr. Ball saw him at about four o'clock in the morning he was in a condition of collapse, with general tenderness over the abdomen, pulse 130, temperature 103° F., and it was evident that perforation of the bowels had taken place. The patient died early Friday afternoon. No positive diagnosis was made in the case until evidence of perforation occurred.

The autopsy showed that the mass which was supposed to be a femoral hernia consisted of a mass of fat, which was situated directly over the femoral ring, and which had apparently dragged down through the ring the hernial sac, which was found just underneath this mass, but the sac did not contain any intestine. It was evident that the apparent hernial mass had nothing to do whatever with the symptoms which occurred during life.

The mass between the anterior superior spinous process of the ilium and the median line consisted of coils of intestine which were matted together, and it was curious to see how a sensation of hardness could be communicated by the mass of intestines containing air. The coils of intestine had been matted together by inflammatory process, and on pushing this aside and exploring the bottom of the abdominal cavity, the vermiform appendix was found lying much farther toward the left than usual, and in a state of gangrene throughout its distal half; a large portion had sloughed away, and a small, hard mass of fecal matter was found to have escaped from the sloughed appendix.

The history of the case seemed to show that perforation of the vermiform appendix took place on Wednesday afternoon, when he first complained of colic, and when there was a small escape of matter, sufficient to set up a certain amount of irritation, but not sufficient to produce very much pain or febrile disturbances, and an effort had been made by nature to limit this mass by inflammation; but suppuration had slowly taken place and a small abscess had burst into the peritoneal cavity and set up general peritonitis.

The two main points in the history of the case were, first, the fact that it ran its entire course without any fever at all. Dr. Ball had not seen such a case, nor was he aware that such a case had been reported. Second, the situation of the tumor was unique in his experience.

It was evident from the autopsy that an operation would not have been of service.

Dr. Ball asked if it was allowable to operate after perforation had occurred and unmistakable evidence of general peritonitis had developed.

Dr. Weir replied that it was, and that an operation under those circumstances constituted one of the recent advances in surgery.

Dr. Ball asked if an operation had been performed after perforation into the general peritoneal cavity had taken place, and general peritonitis had been established.

Dr. Weir replied that it had, and that it had been regarded as allowable, because the result without an operation was inevitably fatal.

Dr. Ball was aware that an operation had been advocated at the outset of perforation of the vermiform appendix, but he was not aware that it had been performed after general peritonitis had developed.

Dr. Weir replied that it had been performed three times, but only once successfully so far as he was aware.

Dr. Polk remarked that laparotomy for abscess had been performed much oftener.

Dr. Weir remarked with reference to fever, that he could recall one case where there was absence of rise of temperature, and there was resonance over the tumor in the right iliac fossa, which went on to suppuration and was treated by puncture with evacuation. Within the last three months he had seen a case in which the mass was situated close to the umbilicus, very much out of the usual location. Dr. Weir thought that these abscesses were due to the escape of fecal contents into the abdominal cavity much more frequently than at one time was supposed, where they were surrounded by intestines and agglutinated, and bound in by inflammatory process.

Dr. Ball thought that was the case in this instance, and did not think the original escape was into the tissues behind the peritoneum, but was into the peritoneal cavity.

Dr. W. M. Polk then read a paper on

ALEXANDER'S OPERATION OF SHORTENING THE ROUND LIGAMENTS.

Thus far the operation had been performed in fifty cases, but the results had left its value still unsettled.

The operation was originally proposed for cases of retroflexion or retroversion, but there were very many of these cases in which it was practically useless.

The operation should be limited to posterior displacement, in which there were no adhesions, but in which there were symptoms directly referable to the displacement: to cases of ordinary prolapsus, and to cases especially of retroversion accompanied by prolapse of an ovary. The operation should not be the sole one in cases with prolapse of the ovaries.

Are there any special dangers connected with the operation? In one case sloughing of the wound occurred, followed by septic peritonitis and death.

There was one danger belonging solely to the operation itself, namely, separation of the tube from its new attachment, the uterus dropping back and dragging the tube with it into the peritoneal cavity.

The difficulties of the operation were simply those of dissection. The rule which Dr. Polk had adopted was to make the incision directly over the spine of the pubis and reach the conjoined tendon before attempting to locate the ring; by following this method he had not had any difficulty in securing the ligament. It was not always easy to invaginate the labia and reach the round ligament.

It was not easy, also, to distinguish the ends of the round ligament, so that it was simply impossible to grasp it with the forceps, but a mass of fatty tissue vessels could be readily seized and traction made upon it which would bring the ligament to view.

Dr. Polk suggested that the traction be made very slowly, and he would not cut off the ends of the ligament after stitching it down. He would prefer, also, to stitch it to the upper surface of the pubic bone rather than to the column of the ring on either side. After stitching the ligament to the upper face of the pubis with silk, he would stuff the vagina with cotton to hold the uterus up as far as possible, and in dressing it would always put a bone drain down to the bottom of the wound for the reason that suppuration seems specially prone to occur in this tissue.

INCUBATION OF SCARLET FEVER.

The President said that since the publication of the proceedings of the Society with reference to scarlet fever he had received the following communication from Dr. Benjamin F. Miller, of Cincinnati, O., to which he had replied that it seemed to him that the period of incubation of eight weeks was out of the question, nor was it necessary in Dr. Miller's case to suppose that the period of incubation was so long as that. So far as he knew, no

case had been recorded in which the period of incubation was so long as five weeks. While it might be possible, though improbable, that the period of incubation might be as long as five weeks, he had explained the development of scarlet fever in the second boy on the supposition that he was not susceptible to the poison of the disease at first, but afterward became susceptible and took it, and that this susceptibility did not arise during the earlier part of the five weeks, when the older boy first came home, but at a period later, and during all this time the older brother was desquamating freely and the younger brother was with him every day.

Dr. Kinnicutt thought it reasonable to suppose that susceptibility to the poison was at its minimum when the second boy was in contact with it at first, but that later this susceptibility was sufficient to enable him to contract the disease.

Dr. Weir suggested that another probable factor in etiology was the lingering of the infection of the disease about the house or articles of furniture, etc., and referred to the case of a child who had scarlet fever, and a second child contracted the disease one year afterward from a doll with which the first child had played and which afterward had been put away in a box.

POISONING BY MERCURIC BICHLORIDE SOLUTION.

Dr. Kinnicutt wished to call the attention of the members to a single point, *apropos* of a subject of discussion at the last meeting of the Society. He had recently read the report of two cases (by Hofmeier, of Berlin) of toxic enteritis caused by corrosive sublimate injections in obstetrical practice. In both cases renal disease had apparently pre-existed.

Bouchard in 1873 had also reported two cases of mercurial poisoning, in one of which parenchymatous, in the other chronic interstitial nephritis was found to be present at the autopsy.

Any disease or condition, such as renal disease, which interferes with the elimination of mercury may well cause exceptionally severe symptoms during its administration; and it seemed to him of great importance to know whether in the fatal cases recently reported, evidence of pre-existing kidney disease had been found. If so, might it not explain the susceptibility shown in these cases to its influence, and hence in the future prove an important guide to the surgeons in its use?

Dr. Peabody remarked that not having had his attention directed to the possible kidney complications he was unable to speak positively.

Dr. Weir said that he was the first to employ mercuric bichloride solution in this country, and at that time the tendency to affect the kidneys was well known, and made him especially careful with reference to the examination of the urine in all cases, to see whether there were any signals of danger, but it did not seem to make any change in the urine. He would like to interject here recent observations made by Volkmann in the treatment of knee-joint cases, where it appeared that carbolic acid solution of three to five per cent. in washing out wounds in children was much more dangerous than one to one thousand or one to two thousand of the sublimate solution.

Dr. Sexton asked whether the physiological effects of the drug had been observed, as when it is taken into the stomach.

Dr. Peabody said that salivation after the use of bichloride solution was exceedingly rare.

Dr. Hunter had seen three cases of salivation following the use of vaginal injections of bichloride solution of the strength ordinarily used.

The Society then adjourned.

The Fruit of Conium is active—the root not at all; hence the inertness of some conium preparations (Orfila-Lessage).

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE NEW LUNACY BILL—THE DISCUSSION ON CHOLERA AT THE MEDICO-CHIRURGICAL SOCIETY—KLEIN V. KOCH—SPEECHES BY DR. KLEIN AND MR. WATSON CHEYNE.

London, March 27, 1885.

The new Lunacy Bill, which has been so long anticipated, and to which I referred in a former letter, was introduced in the House of Lords yesterday evening by the Lord Chancellor, Lord Selborne. In a lengthy speech Lord Selborne gave an account of the present state of the law, and then enumerated the changes proposed. I will briefly refer to some of the more important of these. No person, not a pauper lunatic, or under the guardianship of the Court of Chancery, is to be received or detained as a lunatic in asylum, licensed house for lunatics, or in any place without an order, under the hand of the judge of the county court, a stipendiary magistrate, or a justice of the peace, having jurisdiction in the place where the lunatic is. As at present, certificates of lunacy from two medical men are to be produced, but it is expressly stipulated that one of these is to be, if possible, from the ordinary medical attendant of the patient, and, if not, the reasons are to be stated. The magistrate can refuse to make the necessary order if he is not satisfied with the evidence of insanity on the certificates laid before him. These clauses will make it practically impossible for interested relatives to imprison a sane person in an asylum. The numerous lunacy trials which have excited so much attention during the last few years, have shown that under the present system, viz., certificates from any two medical men and a formal request in writing from a relative, it has been practicable to incarcerate sane persons for, at any rate, a limited time. Moreover, a further safeguard is now proposed. Within a month after the reception of any patient into any authorized establishment, a report is to be made to the Commissioners of Lunacy, and subsequently a special visit to the newly-received lunatic is to be made by the Commissioner in the district. Every order made is to be limited to three years, and then, if required, it is to be renewed annually. Any interested person can send two medical men to visit a patient, and if they report him sane the Commissioners can discharge him. The bill also tends to discourage private asylums, as provisions are to be made in time, in all public asylums, for the reception of private paying patients. After five years no new license is to be granted for any licensed house without the consent of the Commissioners.

The discussion on cholera at the Medico-Chirurgical Society was opened at the last meeting of that body by the reading of a paper by the President, Dr. George Johnson, F.R.S. Dr. Johnson defended with ability his well-known views on the nature of cholera. Choleraic collapse is, he thinks, due to extreme contraction of the pulmonary arterioles obstructing the circulation through the lungs. He regards the thickening of the blood as the consequence—not the cause—of the impeded circulation. He believes the contagium is ultimately expelled from the system by purging and vomiting. That the excessive discharge of liquids from the system is not the cause of the collapse is, he thinks, shown by the fact that in the most rapidly fatal cases there is rather an inverse than a direct ratio between the degree of collapse and the quantity of liquid discharged.

Dr. Johnson's re-statement of his opinions was received with attention, but it was evident that the audience awaited with greater interest the presentation of the respective views of Drs. Klein and Koch, which was to follow. Dr. Klein appeared in person to represent the views of himself and his colleagues on the British Cholera Commission. Mr. Watson Cheyne appeared as an ad-

vocate for Dr. Koch. Mr. Cheyne is the Research Scholar of the British Medical Association, and has acquired no inconsiderable repute as a patient investigator of bacteriological problems. The Biological Laboratory of the Health Exhibition of last year was conducted under his able superintendence. Mr. Watson Cheyne studied the subject of cholera in Paris during the recent epidemic.

Dr. Klein maintained the direct infectiousness of cholera. He denied the infectious nature of choleraic discharges, and referred to cases where water contaminated with them had not produced the disease; and he also mentioned cases in which the disease had been conveyed by linen which had not been soiled by cholera evacuations, and which had not been worn by a cholera patient. Dr. Klein is at one with many Indian medical officers in his views of the direct infectiousness of cholera. Dr. Klein regards the virus of cholera as not present in, or dependent on, the dejecta of cholera, but considers its formation is due to locality, as Pettenkofer maintains. Remarking that the incubatory period of cholera may be as short as a few hours, or even half an hour, he said it was impossible to believe that in such a short space of time micro-organisms could accomplish the result. Dr. Klein is directly opposed to Koch's view of the specificity of the organisms found in the bodies of cholera patients. He dwelt at some length on the researches of the British Cholera Commission and the results at which they arrived. I referred to this part of the subject at some length in a former communication. Dr. Klein made a great point of the non-specificity of the comma-shaped bacillus, and alluded to Dr. Timothy Lewis's discovery of similar bodies in the saliva of healthy persons. This link in the argument was however somewhat weakened by Dr. Klein's admission, later in the discussion, that he had failed in his attempts to cultivate comma-bacilli from the mouth in the same media in which comma-bacilli from cholera cases could be grown. This point, trivial though it may appear, seems to indicate some slight difference between the bacilli from the two different sources indicated

Mr. Watson Cheyne asked Dr. Klein how he explained the outbreak of cholera on an island immediately after the arrival there of a patient suffering from cholera, seeing that, according to Dr. Klein's view, the dejecta contained merely the products of the action of the virus and none of the infective agency itself. Proceeding, he said it was with the bacterial aspect of the question he wished specially to deal. He adhered to Koch's views. The specificity of an organism did not rest merely on its shape, but on its mode of growth and other characters. Long ago, Koch himself showed that the bacillus of glanders was comma-shaped. Mr. Cheyne even went so far as to say that not even a particular mode of growth proved an organism to be pathogenic; it merely served as a means of recognition of an organism. Mr. Cheyne said that the testimony of most observers was that the bacillus was always found in cases of Asiatic cholera. There were discrepancies as to the numbers and site of the bacilli; the only satisfactory way of estimating the numbers present was by the method of cultivation. Mr. Cheyne maintained that observers had found bacilli in every case of Asiatic cholera which had been examined, whether in India, Egypt, Italy, France, or Spain. He described some cases in which he had succeeded in inoculating animals and found comma-bacilli in the intestines in abundance on post-mortem examination.

THE CONTAGION OF SCARLET FEVER.

To the Editor of The Medical Record.

SIR: I take notice of an article in your valuable number of the 28th ult., page 353, on "Scarlet Fever" communicated by a third healthy person. My experience is this: In January of this year I visited a little daughter of Mr. W. L——, aged five years and six months. She had scarlet fever. My visits were made at 10 A.M., three miles from home. I did not arrive home any day until about 3 P.M., or five hours after my visit on this patient. I ride in an open gig, and everybody knows it froze fearfully. Every day and most of the time up here the wind blew. I always removed my two outer coats at home and hung them three rooms distant from my children, or at times left them to freeze in the horse barn. I put on a coat never worn to visit scarlet-fever patients, and then took upon my shoulder "the little white-haired" lass, eighteen months old, who ran to meet me. She was taken with the fever before I had finished my visits of three weeks on the little girl. My little eighteen-months' child had not been out of doors for two months, no one from an infected house had been near my home, for there were but three families in town who had the disease during the year. I either brought the disease home in my hair (which I believe) or in my pants below the region of the bottom of my overcoat.

Two years since I attended a case. One day I drove about one mile, stopped at a house where was a little girl which I did not approach nearer than ten feet, nor did I sit down. In nine days that child had the scarlet fever. The mother said I brought it.

Again, a few years ago I attended one family four miles from home. In driving I wrapped the robes close about my limbs. A month afterward I took my ten-year old daughter to ride, using same lap-robes. In a few days the daughter came out in full scarlet fever, and subsequently fearful dropsy. These facts are stubborn, and to my mind prove that a third healthy person can carry the contagion of scarlet fever.

Yours, etc.,

W. H. MATHER, M.D.

SUFFIELD, CONN., April 2, 1885.

To the Editor of The Medical Record.

SIR: Dr. Baruch's letter on page 353 of THE RECORD calls to my mind an experience of my own bearing on the question discussed by Dr. Baruch. Several years ago, in the winter season, I had charge of two children, smartly, but not very severely, sick with scarlet fever at a house about five miles from my residence, and visited them once a day for three or four days. As the mother had no assistance in the care of the children it was my custom at my visits to take both children on my lap while she made up the bed in which they slept. After my visits I returned home, usually a little before supper-time. The youngest two of my children—about two and four years old—were convalescing from a moderate attack of measles, and were rather fretful at that time of day, and I used to hold them on my lap to amuse and soothe them. In about a fortnight's time they were both taken with a mild form of scarlet fever. There were no other cases in the village where I then resided, during that winter, either before or after the sickness of my children. The circumstances were certainly in this case favorable to my conveying the contagion. At the house where the sick children were I commonly put on my overcoat and mittens directly after giving the children to the mother to replace in bed, and at my home took my own children in my lap almost as soon as I had laid off my overcoat.

Yours very truly,

WILLIAM MANLIUS SMITH, M.D.

SYRACUSE, N. Y., March 30, 1885.

To The Editor of the Medical Record.

SIR: I have a case of scarlatina to report which may serve to answer in part the question of its communicability by a third healthy party. In September, 1879, I was called by H——, a wood-chopper, to see his children. I found him living in a small house upon the summit of a lofty foot-hill of the Adirondacks, one mile from the main road. On reaching the house I found one child already dead and another delirious from scarlatina. I was not aware that there had been scarlatina in this neighborhood, and the almost complete isolation of the

family, none of whom had been away from home in months, left me in doubt as to the source of the contagion.

By making inquiry, however, I learned there had been a case in a family living about four miles distant, and that an old man who had taken care of it had been in H——'s house, and being fond of the dead child, had taken it on his knees and caressed it. He was at that time in good health, nor had he been sick for years. In view of the fact that he had been with the first case during convalescence, and hence during the period of desquamation, I did not doubt that he was the vehicle by which the scarlet fever had been conveyed.

Very truly yours,

F. B. STREETER, M.D.

GLENS FALLS, March 30, 1885.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I send the following, and if worthy of publication give it place: At a meeting of the Society of Practitioners in New York, reported in THE MEDICAL RECORD, March 14th, the question is asked whether a physician who is attending a case of scarlet fever ought to take midwifery cases? Dr. Robinson, in the discussion following, said that he did not think there was much danger of either the mother or child taking the fever. In this connection I have an experience to relate. During the spring of 1884 I was attending cases of scarlet fever and early one morning was called to an obstetrical case, a lady in her third confinement. I had visited scarlet-fever cases the day before, and did not change my clothing but disinfected my hands with iodine and carbolic acid. In three or four days the infant took scarlet fever, but the mother escaped. When the stage of desquamation was well advanced it took measles, the father being down with it, and all in one room, simply because they had no other.

Shortly after, the two remaining children were attacked with scarlatina, the eruption being very full and quite red from the head to the feet. About the fourth day of the scarlet eruption the measles eruption appeared, showing darker elevated spots having the crescentic appearance peculiar to measles. I have no recollection of cases occurring where the two eruptive diseases appeared at the same time in the same individual. What do the practitioners say? J. M. WARD, M.D.

CORNELIA, Mo., March 23, 1885.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from March 20, 1885, to April 4, 1885.

HALL, WILLIAM R., Captain and Assistant Surgeon. Granted leave of absence for twelve months and fifteen days, to take effect when his services can be spared. S. O. 70, A. G. O., March 27, 1885.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. Ordered for temporary duty at Fort McHenry, Md. S. O. 63, Department of East, March 28, 1885.

BIART, VICTOR, Captain and Assistant Surgeon. Leave of absence extended six months on surgeon's certificate of disability. S. O. 77, A. G. O., April 4, 1885.

COWDREY, STEVENS G., Captain and Assistant Surgeon. From Department of the East to Department of the Missouri. S. O. 77, A. G. O., April 4, 1885.

DE LOFFRE, AUGUSTUS A., Captain and Assistant Surgeon. From Department of the East to Department of Dakota. S. O. 77, A. G. O., April 4, 1885.

CRAMPTON, LOUIS W., Captain and Assistant Surgeon. From Department of the East to Department of the Platte. S. O. 77, A. G. O., April 4, 1885.

TORNEY, GEORGE H., Captain and Assistant Surgeon. From Department of the Missouri to Department of the East. S. O. 77, A. G. O., April 4, 1885.

ARTHER, WILLIAM H., First Lieutenant and Assistant Surgeon. From Department of the Platte to Department of the East. S. O. 77, A. G. O., April 4, 1885.

WYETH, M. C, First Lieutenant and Assistant Surgeon. From Department of Dakota to Department of the East. S. O. 77, A. G. O., April 4, 1885.

CARTER, E. C., First Lieutenant and Assistant Surgeon. Granted one month's leave with permission to apply for one month's extension, to take effect upon the arrival of another medical officer at his post. S. O. 30, Department of Arizona, March 23, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 11, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Smallpox.	Yellow Fever.
Cases.								
April 4, 1885	0	5	106	6	207	77	0	0
April 11, 1885	0	3	75	5	185	63	0	0
Deaths.								
April 4, 1885	0	2	19	6	19	24	0	0
April 11, 1885	0	0	12	3	22	31	0	0

SALT.—Our esteemed contemporary, the *New York Medical Journal*, in a recent editorial article not only praises salt-water bathing, but suggests other possible uses of this agent, and especially its employment as an antiseptic and disinfectant in connection with our sewerage system. By putting a few handfuls of salt daily into the basins and water-closets, the sewer-gas odor is in a measure controlled. In view of the threatened invasion of cholera and the asserted value of salt as a prophylactic agent in this disease, the above suggestions are very timely.

THE RELIGIOUS PRESS AND "QUACK" ADVERTISEMENTS.—The "quack" advertisements which are circulated by professedly Christian journals are among the offences which cause intelligent and reverent men to doubt. A specimen of such advertisements is sent to us (from a religious journal having a very wide circulation), abusing the medical faculty and vaccination, and extolling the "Anti-vaccination Mixture." The whole thing is so absurd that we are almost ashamed to notice it, excepting to regret that a well-meaning contemporary should permit such rubbish to appear even in its advertisement columns.—*Lancet.*

WHERE WE TASTE THE DISGUSTING.—The third and lowest part of the tongue, supplied by the glosso-pharyngeal and throat, is the seat of those peculiar tastes to which was given the names of relishes and disgusts It is here chiefly that we taste animal food, fats, butters, oils, and the richer class of vegetables and made dishes. If we like them, we experience a sensation which may be called a relish, and which induces one to keep rolling the morsel further down the throat till it passes at last beyond the region of our voluntary control. If we don't like them, we get the sensation which may be called a disgust.

THE TANNATE OF THE PROTOXIDE OF MERCURY or hydrargyrum tannicum oxydulatum is a remedy for syphilis, introduced by Lustgevten, and already quite extensively used in Germany. It is given in doses of gr. jss. two or three times daily, an hour after meals. It acts quickly and does not easily disturb digestion or produce salivation.

Original Articles.

ENDOMETRITIS FUNGOSA; ITS PATHOLOGY, DIAGNOSIS, AND TREATMENT.[1]

BY JAMES B. HUNTER, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK: PROFESSOR OF GYNECOLOGY IN THE NEW YORK POLYCLINIC, ETC.

THE disease known to us as endometritis fungosa was described by Robert, a pupil of Récamier (*Bul. Thérapeut.*, 1846, tome 21). Récamier himself wrote on the subject, under the title of "Fongosités Utérines," in 1850 (*Union Méd. de Paris.* tome 1, 1850). In 1848 Robin (*Arch. Gén. de Médicine*, xvii.) said of these fungosities: "They are, from an anatomical standpoint, simple vegetations from the uterine mucous membrane, having therefore the same anatomical composition, and enclosing fibroplastic tissue."

Rouyer ("Thèse de Paris, 1848") says: "The fragments made with a curette are generally from three to five centimetres long; from five to six millimetres wide, and from one to five millimetres thick. Their free surface is smooth, and covered with epithelium; the tissue is very vascular. In this hypertrophied mucous membrane there appear granular forms of three kinds, viz.: 1, Granules which resemble small gooseberry seeds, and are opaque or transparent—these raise up the mucous membrane, and form white spherical, almost sessile, projections; 2, masses of a spongy character, like placental tissue; 3, granules about as large as the head of a pin, which are seen *beneath* the mucous membrane. These may attain the size of a pea, and resemble the forms described, except that they are more numerous and regularly distributed.

Nélaton (*Gazette des Hôpitaux*, 1853, No. 17), states that fungosities have two surfaces—a free surface, which is of a rosy red color, and growths resembling the intestinal villi, and an attached surface, the latter having a deep red shade, and suggesting freshly torn tissue.

Ferrier ("Thèse de Paris, 1853") had an opportunity to observe these growths *in situ*, on several occasions, in the dead-house. He describes them as small, spongy, pulpy masses, red or rose-colored, soft, easily detached with the finger-nail, with or without pedicles.

Goldschmidt ("Thèse de Strasburg, 1859") states that Koeberlé found them fifteen times in the cadaver.

Richet, Robert, and Nélaton all took opportunities to study this condition at autopsies. For the gross pathology of this affection we are indebted largely to early French observers, and some after them recognized its nature quite clearly. The German authorities have investigated more thoroughly the microscopical anatomy of the subject; Olshausen (*Archiv für Gynakologie*, vol. viii., No. 1) having contributed the most important paper.

Among those who have written on the subject are Aran ("Mal. de l'Utérus"); Courty ("Mal. de l'Utérus"); Gallard, Ruge and Veit; Nonat ("Mal. de l'Utérus"); and Winckel, under the title of "Adenoma Papillosum Diffusum Corporis Uteri." The disease does not seem to have been studied or appreciated by the English authorities. In this country it has long been recognized and successfully treated.

[1] Read before the New York Academy of Medicine, April 16, 1885.

There is some confusion as to the term "fungosity." Olshausen writes of "endometritis hyperplastica chronica vel polyposa;" Hegar and Kaltenbach include the condition under "endometritis;" Weber refers to it as "endometritis hemorrhagica;" Slavjansky employs the term "metritis villosa;" Courty treats of granulations and fungosities, and considers fungosities a development of granulations. Throughout his whole chapter on this subject, Courty singularly confounds fungosities of the uterine cavity with erosions, and with hypertrophy of the follicles of the cervix. According to my experience fungosities proper are never found in the canal of the cervix, though often abundant just above the boundary line between the cervix and the body of the uterus. They are certainly never found, as Courty seems to believe, "commencing at the os uteri."

Pathology.—If the lining membrane of a uterus which is the subject of fungosities be gently scraped with a blunt curette there will appear, together with some blood-clots, a number of small, pink, firmly organized bodies, sometimes gelatinous, resembling small polypi, and varying from the size of a pin's head to that of a small pea. I have seldom found them to exceed five millimetres in size, and, as a rule, they are much smaller. They cannot be easily broken down by the finger, and are very easily distinguished from blood-clots when put into water. Neither the size of these growths nor their number is in proportion to the amount of hemorrhage to which they may give rise. The scraping, if carried over the whole surface of the uterus, will generally exhibit a few whole fungosities and a quantity of fragments, mixed with blood-clots. The true fungosity is always of a pale pink color after removal, but is probably congested while attached to the mucous membrane of the uterus, as the structure is highly vascular. Aran divides fungosities into sessile tumors, with broad bases, and pediculated or polypoid masses. Mundé (*Edin. Med. Jour.*, April, 1878) speaks of three varieties, including "uniform hyperplasia of the entire mucous membrane," which, pathologically speaking, is questionable. The difference between sessile and pediculated fungosities is one of form only. All fungosities consist essentially of a hypertrophy of the mucous membrane, in the form of papillary growths having a distinct fibrous basis, and covered by a single layer of cylindrical epithelial cells. I have examined a large number of specimens microscopically, and have often found these characteristics so distinct, and accompanied by so great an increase in the size of follicles, as to offer some ground for considering them new specimens, which might be regarded as adeno-papillomata. The abundant vascular supply of these fungosities has been well described by Olshausen, who also notes the constant presence of numbers of leucocytes, which not only crowd the interstices of the fibrous tissue which forms the bulk of the fungosities, but are also found abundantly in the surrounding mucous membrane. The presence of these white blood-corpuscles in unstained specimens often gives an appearance which it is extremely difficult to distinguish from that of round-celled sarcoma. De Sinéty (Paris, 1879) is the only author who has laid stress upon the close resemblances of fungosities to true granulation tissue. He says: "In other cases the fungosities are specially constituted of embryonic tissue with few blood-vessels. There are only traces of the glands, and some remains of more or less degenerated epithelium. We have then to do with a truly inflammatory tissue, and comparable to

that which remains upon an exposed wound. At certain points there are islands of degenerated elements which are not colored by reagents, and are analogous to those observed in foci producing pus." This statement is important, as showing that we have to deal with something more than simple hypertrophy. Thomas, in using the term "fungous degeneration," does not mean to imply that there is any process akin to degeneration in the development of fungosities, which are really local hypertrophies of the uterine mucous membrane. Fungosities are never friable, and never show evidences of degeneration. They are not homogeneous on section, and contain a good deal of fibrous tissue.

The question naturally arises, why the hemorrhage should be so great, as we know it to be clinically, from a cause apparently so trifling. The amount of hemorrhage will not appear excessive if we consider the extent of surface from which it springs. In normal menstruation the escape of blood occurs because of the fatty degeneration of a portion or of the whole of the epithelial lining of the uterus (Kundrat, Leopold, Engelmann). The epithelial covering of these fungosities probably undergoes the same change as that of the rest of the mucous membrane. In the diagram before you, which is probably not exaggerated as to proportion, the distance from A to B is about six inches. The surface of this fungosity measures ninety-six inches; so that it is evident that the superficial area of the cavity of the uterus may be enormously increased by the existence of a small number of fungous growths. The extreme vascularity of the growths under consideration is not apparent in sections of specimens that have not been injected. The opportunity for obtaining such specimens is very rare. The question of the cause of the prominent symptom, hemorrhage, has been avoided by all the authors I have consulted who have written on this subject.

Microscopic appearances.—The actual appearance of these growths under the microscope has not been satisfactorily described, notwithstanding the vital importance of distinguishing between endometritis fungosa and malignant disease of the uterus. Unaided by the history and clinical features of a given case it is not always possible, by the microscope, from a single small specimen, to make an absolute diagnosis, even for the most experienced microscopists. In a typical case, and under favorable circumstances, there would be little difficulty in doing so. While a diagnosis of sarcoma or epithelioma may often be made from the examination of a single specimen, it may be necessary to examine a number of specimens in order to certainly exclude those diseases and pronounce a diagnosis of an innocent affection.

The papillomatous masses are absolutely characteristic of fungosities, even if there should be no enlarged glands and other appearances characteristic of uterine mucous membrane. This, taken in connection with the amount of fibrous tissue, the glands, etc., will generally suffice for a diagnosis. On staining, the smaller size and irregular distribution of the leucocytes will exclude sarcomatous tissue. In cases where characteristic sections cannot be obtained the diagnosis must be guarded.

According to Olshausen, microscopical examination shows a greatly hypertrophied mucous membrane with increase of all its elements, dilated follicles, enlarged blood-vessels, and great cell-infiltration of all the connective-tissue. There are large dilated blood-vessels, and around them many white blood-corpuscles. Around the follicles are spindle-cells arranged in regular lines. "These," he says, "prove the chronicity of the affection."

I have quite recently had an opportunity of examining, post-mortem, a perfect specimen of fungosities *in situ* that presented the appearance of very small dentritic masses, pale and shrunken, covering the greater part of the anterior wall of the uterus. A number of sections made by Dr. H. C. Coe, through the entire uterine wall of a similar case, including the basis of the growths, showed conclusively that there was no line of demarcation between the normal hypertrophied tissue, but that the uterine mucous membrane was continuous with that covering the fungoid masses. The submucous connective-tissue extended directly into the masses, giving an appearance suggestive of the benign growths in the bladder figured by Thompson as "fibro-papillomata."

Important as the microscope is to enable us to form a diagnosis of this affection, much care and patience is necessary in its use. A hasty examination of a single section, especially a fresh one, is by no means sufficient. Specimens should be examined both fresh, and also hardened in alcohol, and stained. At least a dozen different sections should be looked over carefully and compared with each other, or other specimens and plates. Such an examination, together with the history of the case, will generally enable us to make a positive diagnosis.

Symptoms.—The principal symptom of this form of endometritis is menorrhagia. Rouyer makes the questionable statement that pain is always present, and that it is generally unilateral, radiating from the iliac region to the sacrum and hip of the corresponding side. I have found pain to be rare as a consequence of the existence of fungosities. As a rule, the hemorrhage consequent upon fungous growths is a menorrhagia—that is, it consists in an increase of the quantity of the normal menstrual flow, and especially in a lengthening of the period, which instead of five may last eight or ten days or more. In sarcoma there is generally a metrorrhagia, which occurs independently of the menstrual period, and which often breaks up entirely the menstrual rhythm. A long train of symptoms follow, but they are in nowise different from those common to anæmia from other cases.

In some cases there is in place of hemorrhage a constant discharge of serum, perhaps only tinged with blood. The subjects of such watery discharges lose flesh and strength and become anæmic, as though the loss were of blood.

According to Olshausen the increased flow due to fungosities often comes on suddenly in women previously healthy, and causes an anæmia, as a result of which there is an absence of menstruation for several months. This is directly contrary to my experience.

Lusk reports a case (*Am. Jour. of Obstet.*, January, 1878) which died from progressive cachexia, probably from the existence of fungosities. Dr. M. D. Mann, who examined the uterus, post-mortem, pronounced the case one of "villous degeneration of the uterine mucous membrane." He says of the specimen examined (Trans. Obstet. Soc., *Am. Jour. Obstet.*, January, 1878, p. 133), "it consists histologically of structureless basement substance containing great quantities of small round cells and nuclei, and portions of uterine follicles and vessels."

Etiology.—The growth of fungosities seems to be generally a result of chronic congestion of the uterus. It is commonly found in cases of subinvolution. In unmarried women it is often a consequence of neglected retroversion or retroflexion. In cases of laceration of the cervix, where there is much hypertrophy of tissue, there is commonly an interference with the circulation, which, if sufficiently prolonged, promotes these vascular growths from the endometrium. They seem to result from a moderate amount of congestion, as from a mild form of endometritis, long continued, rather than from the more severe or acute forms of that disease. They have no connection whatever with gonorrhœal or syphilitic infection, as far as I have been able to ascertain. They occur usually during the child-bearing period, but may be found before and after that time. It is some aid in diagnosis to remember that sarcoma, as a rule, does not occur till between thirty-five and forty.

One of the causes of hyperæmia of the uterus is the existence of fibroid tumors in connection with that organ. Hence fungosities are often found associated with fibroid tumors, and in some cases are the chief cause of excessive hemorrhage. They should always be suspected in cases

of fibroids, as their removal may be of great temporary benefit to the patient.

Differential diagnosis.—The conditions with which fungosities are liable to be confounded are :

1. Benign growths, *A.* Submucous polypus; *B.* Adenoma of the uterus; *C.* Benign papillomata; *D.* Villous degeneration of the endometrium; *E.* Placental or decidual remains.

2. Malignant growths, *A.* Carcinoma of the body of the uterus; *B.* Round-celled (or diffuse) sarcoma.

Benign Growths.—A. Fragments of soft myxomatous polypi removed from the uterine cavity sometimes resemble fungosities on gross inspection. Under the microscope the loose fibro-muscular tissue, the enclosing layer of epithelial cells, the enlarged blood-cells, and the free leucocytes give an appearance which might easily be mistaken. A few stained sections of the suspicious masses will bring out the well-marked papillary remains, and clear up the diagnosis. The rare form known as "channelled polypus" is distinguished by the presence of a large number of cavities of a size never seen in true fungosities. Klob describes a vesicular polypus which seems to be of the same character as the variety just named. Polypi are more limited in number, and more localized. They are often found in the cervix, while fungosities are not.

B. Adenoma of the uterus is a rare condition, and the descriptions of it are vague. Savage seems to regard it as not uncommon, but he evidently confounds it with fungosities.

C. True benign papillomata are said to be confined to the cervix, while fungosities are, in the opinion of all authors except Courty, limited to the body of the uterus. The microscopical differentiation of these two conditions would be difficult, if not impossible. It is a question whether some of the large fungoid growths should not be regarded as true morbid growths rather than simple hypertrophies.

D. Goodell refers to a condition which he calls villous degeneration of the endometrium, the same being described by Hirschfeld as "cylindrical cell adenoma," and by Winkel as "adenoma papillosum diffusum corpus uteri." The cases described by Goodell were probably either villous cancer or simple fungosities.

E. The diagnosis of fragments of placental polypi or retained decidual remains is not easy. The embryonic cells of fœtal remains are larger than those covering the fungoid masses. The cells covering fungoid masses are cylindrical, and the connective-tissue basis is firmer and more pronounced than in the chorionic villi. The latter are generally longer and more delicate, and have clubbed rather than accuminate extremities.

Malignant Growths.—A. Epithelial or medullary carcinoma of the body of the uterus is so different in its history, and so different microscopically, that there is little danger of confusion. The cells of an epithelial type, infiltration, excessive degeneration, alveoli, fragments, etc., are sufficient to make the diagnosis of carcinoma easy.

B. Round-celled sarcoma of the uterine mucous membrane is more likely to be mistaken for fungosities than any other condition. Sarcoma of the body of the uterus is not so exceedingly rare as it is stated to be by Dr. Mundé in his article already quoted, in which he says that Schroeder has found only sixteen cases reported in literature. I have seen seven cases in my own practice, and in that of Dr. Thomas, in the Woman's Hospital and elsewhere, I have seen twice as many. Dr. Coe, Pathologist to the Woman's Hospital, has examined six cases, in which there could be no doubt of the diagnosis, within the present year. Mundé believes that localized fibro-sarcoma (the hard variety) is the more frequent. In this my own experience is not in accordance with his. I believe sarcoma is not so very uncommon, but that it is often overlooked; and it should always be suspected in cases where we exclude fungosities and carcinoma. The symptoms of sarcoma may be very similar. Virchow ("Onkologie," vol. ii., p. 350) thinks many innocent hyperplasiæ of the mucous membrane are mistaken for sarcoma, but he gives no differential diagnosis. In sarcoma scraping generally yields a considerable quantity of soft, brain-like material, breaking down readily upon handling, homogeneous on section, frequently showing marked degeneration (pus, etc.). It never appears in distinct formations, but the fragments are always irregular in shape, whatever their size may be. The difference is marked, even to the naked eye, and is rendered very distinct by a lens of low power.

Microscopically sarcomatous tissue is homogeneous in appearance, being entirely made up of round cells with a fine stroma. The cells are mostly somewhat larger than leucocytes and have a large central nucleus. Transitional forms, "alveolar sarcoma," "sarcoma carcinomatodes," may be found in the uterus, the cells assuming an epithelial type, and being arranged in alveoli. These appearances are of course never seen in fungosities. In the examination of fresh and unstained specimens there is a liability of error, because in both cases the field is filled with masses of round cells.

DIFFERENTIAL DIAGNOSIS.

Symptoms.	
Fungosities.	*Sarcoma.*
Little or no pain.	Considerable pain.
Menorrhagia the rule, metrorrhagia the exception.	Menorrhagia and metrorrhagia usual.
Discharge generally odorless.	Discharge often offensive.
Gross Appearances.	
Pale pink color, semi-transparent, sometimes gelatinous.	Grayish white, brain-like.
Distinct formations, of firm consistency; undergo no degeneration.	Soft, friable, amorphous, and prone to degeneration.
Microscopical Appearances.	
Single layer of normal columnar epithelium and irregular groups of leucocytes.	Structure entirely cellular, single nuclei.
Stroma considerable and not intercellular.	Stroma slight and intercellular.
Papillomatous arrangement.	No papillomatous arrangement.
No infiltration of healthy tissue.	Healthy tissue invaded.
Surrounding mucous membrane normal.	Surrounding mucous membrane destroyed.

Clinical differences between fungosities and sarcoma.—The thorough use of the curette in cases of fungosities is followed by little or no hemorrhage. If the case is one of sarcoma, there is apt to be much bleeding for several days after the use of the curette, the condition of the patient is aggravated rather than improved, and there may be considerable pain lasting for several days. In case of simple fungosities, if they are thoroughly removed by the curette, and if the cause of the congestion of the mucous membrane be remedied, the patient is often permanently cured after a few months. In sarcoma similar treatment is of no avail whatever to arrest the tendency to hemorrhage, nor does the patient in the latter case improve much under tonics, food, and general hygienic measures. Fungosities recur after six or eight months if the original cause remains, but for a period the patient is free from hemorrhage, and gains health rapidly. Sarcoma recurs after removal, and after mere scraping with a blunt curette it often assumes a rapid growth.

Treatment.—The disease having been recognized and a positive diagnosis made, the treatment of the existing condition—the fungosities—is very simple and satisfactory. The cure of the condition that gives rise to a hyperæmic condition of the uterus is a very different and much more tedious affair, and must obviously be adapted to each individual case.

It is not usually necessary to dilate the canal of the cervix in order to use the curette. The presence of any growth or body within the uterus tends to cause a patulous condition of the cervical canal. The operation of curetting should be done under the influence of ether. The patient being on the side, a Sims speculum is introduced, and the canal of the uterus is cleansed by the

use of cotton on the ordinary applicators. The whole surface of the uterus is then gently scraped with the blunt curette, the curve of the instrument being changed so as to enable every part of the cavity to be reached. Cotton should again be used to remove the loose fungosities and to cleanse the uterus. An application of the strong tincture of iodine (Churchill's), or of strong carbolic acid, should then be made to the whole surface, a little absorbent cotton placed in the vagina, and the patient put directly to bed, where she should remain for two days, or longer if there be any pain.

The operation may be done without anæsthetics, but it is almost always painful, and it is not likely to be done so thoroughly.

Apart from the effect of the curette on the growths in the cavity of the uterus, it has an excellent effect on the congested uterine mucous membrane, and has been recommended as a means of cure. Dürelius, assistant to Martin, of Berlin, reports sixty cases of pregnancy, occurring in women who had been curetted—forty-nine of them for endometritis.

Dr. Clinton Cushing, of San Francisco (*Western Lancet*, August, 1882, p. 340), recommends the blunt curette in the treatment of hemorrhage from congestion of the uterus, and considers it especially valuable in cases of hyperplasia of the body of the uterus, or subinvolution, its use in such cases being followed by marked improvement.

Patients should be warned not to expect immediate improvement. The first period after curetting is often quite profuse, and it is not till the second or third that there is marked improvement.

If done only in suitable cases, with due preparation, proper regard to cleanliness, and with antiseptic precautions, and if the patient is put in bed immediately afterward, and kept quiet by morphine if there is much pain, I consider the operation of curetting little more hazardous than the passage of the uterine sound, which in certain rare cases has proved exceedingly dangerous.

Contra-indications.—The curette is on no account to be used in case of recent pelvic inflammation or any degree of parametritis. Nor should it be used without thorough preparation in cases where the uterus is so sensitive that it will not tolerate the passage of the smallest probe. Such cases should be prepared by the abundant use of hot water, and should be watched very closely after the operation.

The curette.—A few words in conclusion as to the instrument known as the curette.

Récamier's curette, though not described by him in his article on fungosities in 1850, was doubtless a cutting instrument. It was first a steel scoop, and afterward a loop of flat steel, sharpened on each side. It has recently been claimed in England that Récamier's instrument was blunt, but no evidence is given in support of the statement. Récamier speaks of it himself as the *sonde curette*, and speaks of taking out with it a tablespoonful of fungosities. He refers to the operation as *la cathéterisme utérine*. He speaks of having first used the curette, and then having applied the cautery, and also of having had unpleasant symptoms afterward. He reports the removal of a fibrous polypus by means of his instrument. The introduction of the curette met with much opposition, and Récamier seems inclined either to apologize for it, or to stand on the defensive.

Trousseau (*Gazette des Hôpiteaux*, 1856) says the instrument was so sharp that Récamier perforated the uterus with it on three occasions.

Olshausen condemns Récamier's instrument as dangerous, and recommends that of Sims; he speaks of Récamier as being very harsh in his methods.

Both Sims' and Simon's curettes were of steel, and had sharp cutting edges. About the year 1870 Dr. Thomas devised the blunt curette, and with slight modifications in shape that instrument has been very generally adopted in this country. It has nothing in common with the sharp curette except the name. The name being derived from the French verb *curer*, to cleanse, is more appropriate to this instrument than to one capable of cutting. The introduction of this blunt curette has made the treatment of ordinary fungosities safe and simple.

For general purposes the blunt curette should be of two sizes. The smaller one is an oval loop, one-fourth of an inch wide, outside measurement. This is used chiefly for diagnostic purposes. The larger one is three-eighths of an inch wide. Both are made of copper or soft metal, with a shank that can be adapted to the curve of the uterine canal, the entire handle being nine inches long. For obstetrical purposes they are made larger, and with much longer handles. Many modifications of the blunt curette have been recommended, but the bluntness is the essential feature of Thomas' instrument, and so long as that is preserved the precise shape of the instrument is of little consequence, provided it will reach every portion of the uterine cavity without the use of force. Emmet's curette forceps is a different instrument, and is intended to crush the fungosities without the possibility of danger to the healthy tissue. It was devised to avoid the evils sometimes consequent on even the most careful application of the sharp curette. Those dangers do not belong to the blunt curette, which, as has been said before, with proper care can do no more mischief than the passage of the sound. The therapeutic uses of the blunt curette were fully discussed by Dr. Mundé in a paper published in the *Edinburgh Medical Journal* in 1878. A paper on the same subject was read by Dr. George T. Harrison before the New York State Medical Association, November 19, 1884, and published in the *New York Medical Journal*, December 20, 1884, and is, as far as I know, the latest addition to our scanty literature on this subject.

A NEW HABIT.

By A. G. BROWNING, M.D.,

MAYSVILLE, KY.

UNDER the above head, in THE MEDICAL RECORD of March 14th, you notice an article by Dr. J. E. Clark, in the *Detroit Lancet*, upon the chloroform habit. You quote Dr. Clark as saying "that such a habit is becoming prevalent is scarcely known outside of the profession and the life-insurance companies," and supplement this by saying "that the existence of such a habit is probably unknown to most medical men, and we regret that some facts were not given that would establish solidly Dr. Clark's rather loose assertions."

I do not aim to present the amount of fact necessary to supply this omission, nor to do more than add my feeble support to the assertion that such a habit does exist, and fortify it with the facts at command.

I will premise that this communication was in course of preparation when the article referred to caught my eye, and invested the subject with new interest, since others have observed a matter to me full of mental inquiry and speculation.

If by "habit" we accept the definition "temperament or particular state of body formed by nature or induced by extraneous circumstances," then I have, within a few years, encountered quite a number of instances of chloroform habit, as well defined, peculiar, obstinate, and distressing as that induced by opium, chloral, or other drug.

At the risk of being tedious, I will detail the following:

I was called to a young lady at a large female seminary. The odor of chloroform met me on entering, and the sight of the patient told the rest: she was deeply but not dangerously anæsthetized, and the usual means promptly restored her. Upon retiring she had poured some chloroform upon a napkin for inhalation from a six-ounce bottle, which she loosely corked and placed beneath her pillow. It had flowed away, and in her

helpless intoxication she had followed the fumes to their source, and drawing the clothing tightly about her head, was sleeping her life away when found. It was regarded a first offence by those about; but there was that in her manner and appearance suggesting to me a vice, and her further confidence gave to me this history: She had been, against her will, at this particular school about two years. She acquired with difficulty; study was absolute labor and required "midnight oil," only to be behind in her class at last. Everything became hateful; she grew fidgety, nervous, wakeful; she thought of chloroform, smuggled it, and for more than a year had gone to sleep nightly under its influence without detection till now. She vainly strove to free herself, but without success for even so much as one night; she assured me the days had grown to be weeks long, passed in miserable waiting for the stolen oblivion. She was rapidly becoming a mental and physical wreck. I ruthlessly, perhaps rashly, cut the knot; from that night, in spite of sobs, tears, and entreaties she got no more chloroform. She was removed from school, from all study, and to the country. This of itself did much toward recovery, and with returning will-power the habit was broken after a year or more, the thought even, or the faintest odor of chloroform producing a shudder of disgust.

I had not reached home from my visit to this lady when a messenger asked me to see a gentleman who had taken "too much chloroform." He had "come round" before my arrival, and laughingly remarked upon the "much ado about nothing." But his anxious wife revealed the situation by saying, "he never went to sleep without it," and appealed to me for advice and assistance, graphically putting it "that he was becoming worse than any old drunkard." A few months later he sought me voluntarily, and I then realized the full force of his wife's expression. He looked the drunkard to the life, with his bloated face, jaundiced eyes, inveterate retching, and general collapse. He was just off a chloroform debauch. Five years before, he had sought relief at night from a tormenting neuralgia, by inhalation of chloroform. His remark was that he "took to it as a duck does to water;" odor, effect, everything was just heavenly, and it became a nightly indulgence, varied by an occasional "spree," when for days he would consume incredible quantities, never letting up till his stomach, revolting, would stand no more, and horrible nausea, with vomiting, would make him vainly wish for death in any shape. A staggering convalescence, with temporary loathing for the drug, ended in a sure and early return to it, when the same disgusting routine was gone over again and again. He was just up from this experience, and was ripe for suicide or what not. This man made two desperate attempts upon his life within a year of treatment, during which I had heartlessly interdicted the coveted drug. A year more and I lost sight of him. I don't certainly know whether he ever lapsed into the habit.

A lady had taken arsenic; there was no time to learn more, and this seemed enough. I thought she would have her way, and die; but she didn't, and told me this story: She was one of a company of theatricals, from Chicago. Three years before, she took chloroform for extraction of teeth. She then and there met her fate: she was charmed, fascinated, and would thereafter extemporize or feign ailings or pain demanding its administration, till, in time, throwing off all disguise she adopted the nightly habit, and finally became a confirmed chloroform fiend. Her husband's remonstrances were vain: she was subjugated, and a willing slave. Hoping travel might avail something, he induced her to join with him a strolling company. Short time proved this a mistake; there came the bickerings, jealousies, and other too frequent drawbacks to this kind of life, and what had been only a weakness gravitated into sheer desperation to escape temporary but oft-recurring annoyance. She became, mentally and physically, unfit for the boards, and her husband, pardonably desperate, denied her the drug and stuck to it. With it, he knew she must die; without it, she didn't care to live. She compromised on arsenic, which gave me this little life-story. I approved her husband's course, and she got no more chloroform. She finally grew better, vigilance was relaxed, when one day, six weeks after her arsenic, she was permitted to walk alone. She threw herself into the river, was again rescued from herself, and taken, a maniac, to an asylum. I heard no more of her.

A bright man, an attorney, was up to the regulation standard in all things but one: he would, now and then, infringe some worse man's prerogative and get on a drunk. A week's debauch and his legal stomach, asserting its physiological rights, would have no more of the vile stuff, and he would vomit himself into—not sobriety, but inhalations of chloroform. He revelled in this for a season, till the viscus aforesaid, perceiving the trick, rebelled again, and he began repayment of the old debt with interest compound. And so on till chloroform in time supplanted whiskey; there was a change of masters. Upon the slightest provocation, or just no provocation at all, omitting the ardent, he would go upon a chloroform "spree," and for days and weeks vibrate between pitiful coherence on the one hand, and disgusting stupor on the other. This continued for years, sapping all of value in the man, till one lucky day the inevitable overdose came, bringing him face to face with death, from which he was rescued with difficulty. There was just enough left of him to respond to fright; he did respond, and vigorously. He began to think, and, thinking for the first time in his later years, was generously helped to act. After a long and fearful struggle he mastered the foul craving, resumed his normal status, sought and found the old avenues to popular favor, and died some time since with only sad memories of his chloroform habit.

I have under occasional care a case exciting interest and appealing to sympathy; and as regards the latter, is so far rare. The gentleman is of mature age, intelligent, respectable, as free from current vices as we find men; is heir apparent to, but not yet in possession of dyspepsia, his family having suffered from it through successive generations. In consequence he is easily unbalanced in spirits, going, with no visible motor, from attic to basement at a bound. With an invisible craving for an undefined something, he has thus far escaped the Scylla of drink, only to run into the Charybdis of chloroform. Not daily, as in the other cases; but there are times when the heavens, hung with black, close in upon him, the world grows forbidding and dark, he becomes gloomy, wretched, despairing, and takes to chloroform as the drunkard to his cups. And it is a genuine debauch; he takes it for days, till the stomach revolts, when nausea and vomiting rend him for a time, and the eruption is over. He has this *molimen*, if the term applies, every two or three months, and when present, the impulse to take chloroform is simply irresistible, nor will any known drug supply its place. In the interval the odor of chloroform is nauseating in the extreme, and he couldn't be induced to receive it. He berates himself roundly for his weakness, but claims there are times when experience avails nothing, will-power is in abeyance, the appetite possesses him utterly, and he is helpless to resist. He has been a sufferer for eight or ten years.

I could cite yet other instances, quite as much in point, but these are more than space allows; fewer, however, might not contribute the facts, and these are facts, and I must think pertinent. Brother practitioners have assured me of a like experience, in a degree, and drug clerks can reveal histories of which we know nothing.

Beyond question there is an existing chloroform habit—a something in which deluded men take into their lungs ethereal devils to steal away, not only their brain, but all over which it presides. If not as frequent or general as that of opium or chloral, it is far more so than is suspected, and is becoming a matter for consideration,

restraint, and removal, by moral suasion, medication, legal process, or all combined, so that it be stamped out. It is a habit, too, minus the shallowest plea ever extemporized for the use of alcohol; continued indulgence in which reduces life and its every ennobling impulse and attribute to the lowest semblance even of mimicry. Idiocy is pitiable: confirmed *chloroformism* is lower in the scale, and revolting. There is, in fact, nothing comparable in utter loathsomeness to a chloroform *drunk*, pure and simple. The drivel and dribble inseparable from its administration by the physician, is one thing, and offset by necessities in the case—hallowed even by present suffering, and sanctified by the end in view. The same, wantonly induced, the offspring of a depraved and vicious appetite, without apology or reasonable excuse, and perpetuated through days with superadded vomit and general nastiness, is quite another, and too disgusting for accurate description, too loathsome for endurance. The man maudlin drunk on the meanest whiskey, however revolting, is a prince compared with such! For he *was* jolly once; the chloroform drunkard never!

But it goes further: the process is one of thorough emasculation — death, with geometrical precision, to every function; somatic death with no incidental solemnities, and but a shadow for final sepulture. Every physiological process, without exception, goes down in the wreck. So surely is this so, that were I commissioned to destroy my kind—to sap their morals, dwarf their intellects, wither their physique, and estop reproduction, the habitual use of chloroform, as I have known it practised, would leave nothing to be desired.

I know whereof I speak; do not overdraw, nor can I think my experience wholly exceptional upon a more general comparison of notes.

In this rambling communication I have aimed at nothing but a narration of facts—no attempt at theory or speculation. I will add here that in nearly every instance the chloroform habit has seemed to replace the appetite for drink. I mean that the craze for chloroform has developed, in nearly every case, in individuals who, though strictly temperate themselves, come of a line of drinkers more or less remote. Is this a matter of hereditary descent? another evidence that the "sins of the father are visited upon the children, even to the third and fourth generation?" Temperance reformers may make a note.

March 20, 1885.

DYSPEPSIA SEPTICA AND SCHAFFER'S ASEPTIC TREATMENT OF THE ALIMENTARY TRACT.

By ACHILLES ROSE, M.D.,

NEW YORK.

Our food, mostly composed of organic substances, after entering the alimentary canal, may, under certain conditions, become decomposed in a way differing from proper digestion and physiological assimilation. Fermentation, putrefaction, and kindred processes then occur, and these anomalies are probably almost always caused by invasion of micro-organisms.

There are various ways by which such invasion may occur, a favorite place from which they proceed is the cavity of the mouth. There we find, within carious or between healthy teeth, or on or among the soft parts, great colonies of fungi which, together with the secretion, enter the stomach and further on the intestine, producing their ill effects, reducing gradually even a very resistant constitution, but doing injury especially when nutrition is already impaired, or when constitutional or organic diseases pre-exist.

The cavity of the mouth is only cared for by individuals of the better classes, and it seems to me that too little attention is paid to the teeth and the mouth when we are dealing with patients of the lower walks of life; they should be instructed in this essential of the aseptic treatment.

The pathological conditions of the alimentary tract caused by invasion of micro-organisms may manifest themselves as independent diseases, as, for instance, catarrh of the stomach or intestine, typhus, typhoid fever, dysentery, cholera, etc.

All these affections, though differing in degree, or according to the nature of the invaders, or according to the intensity of the consequences which these invading micro-organisms have produced, form, after all, only one kind of disorder, that is, a septic state, *dyspepsia septica*.

A number of more or less severe disturbances in the alimentary canal form part of nearly every acute or chronic disease, and where the symptoms of the remote affection attract more attention than the accompanying septic process in the alimentary tract, the latter may decide the gravity and the extent of the remote disease.

The modern standpoint, from which one regards certain pathological conditions of the alimentary canal as septic, gives us a better understanding of the therapeutical effects of certain remedies on this organ, and facilitates the selection of the best therapeutical measures.

There are a great many means which aid to render digestion aseptic. The ordinary diet instinctively is based in a great measure on this principle. Extreme temperature of solid or liquid food, ice and ice-cold drinks, or hot liquids (treatment of dyspepsia by hot water), the spices, carbonic acid in mineral waters, etc., are antiseptics.

Looking over the many remedies more or less certain in their antiseptic action, we find the following list: Certain metallic salts, such as bismuth, silver, zinc, the different preparations of iron, several bitters, quinine, nux vomica, the alcoholic preparations of tar, the salts of different alkalies—which latter act not only as antiseptics but also as evacuants—and finally, muriatic acid. From our standpoint we may explain some of the physiological and therapeutic effects of the muriatic acid by the fact that chlorine is one of its constituents. It is most probable also that some other preparations act in the same manner; thus we perceive that persons, after the use of iodide of potash, appear to be in a better state of nutrition. The good effects of bromide of potash in certain gastric troubles may likewise have to be attributed to the fact of its being an antiseptic, instead of finding an explanation under the head of "Nerve Therapeutics."

It has been the erroneous impression that iron, when given as a tonic, was taking part directly in the formation of blood. As a medicine it renders the process of digestion aseptic; the alimentary tract being disinfected, nutrition is improved; iron contained in the different articles of food is assimilated to take part in sufficient quantity in the formation of blood, and anæmia disappears.

Muriatic acid is the natural disinfectant of the stomach, and bile acts similarly in the intestine.

The artificial means employed to render the alimentary canal aseptic, when the natural disinfectants are wanting or inadequate, should not themselves cause any disturbing effect on the chemical act of digestion, or on the system in general. Some remedies may render digestion more or less aseptic; they may relieve some pathological symptoms, but assimilation may, after all, leave a great deal to be desired.

Ever since the year 1872, I prescribed in all cases of chronic catarrh of the stomach, and chronic gastro-enteritis, subcarbonate of bismuth and calcined magnesia combined, generally ten grains of each, to be taken half an hour before each meal, and in most cases I succeeded without employing any other means, without being scrupulous in regard to diet. In many cases my patients were domestics, employees, or such, who had to take their meals in restaurants or boarding-houses, and the scrupulous diet, so much insisted upon in treatises, they could not observe.

Giving bismuth and magnesia, I practised aseptic treatment before I was aware of it, before we had learned by

Kocher's publication of the excellent antiseptic qualities of bismuth.

To-day I am inclined to devote my attention to another antiseptic in the treatment of gastro-enteritic affections, and this is the yellow oxide of mercury, recommended by Schaffer.

Dr. Ludwig Schaffer, surgeon on board of an Austrian man-of-war, with a crew of two hundred and seventy-eight men, traversing the tropics twice within six months, had opportunity to study the influences of high temperature combined with moist atmosphere, which manifested themselves in loss of appetite and derangement of digestion, sometimes with serious complications. The bill of fare for the men, nutritious enough but offering very little variety, and only calculated for young, strong, and healthy stomachs, gave less and less satisfaction every day. The sultry night air interfered with sleep, and the men's state of nutrition became conspicuously impaired. All these cases thus affected improved and were cured by the use of hydrargyrum alone. After this favorable result Dr. Schaffer did not wait until derangements of digestion and nutrition assumed a serious extent, and obliged those affected to report for the sick list; but he held weekly sanitary inspections of the crew, and gave in more than fifty cases, as a prophylactic measure, generally one, and in rare cases two, centigrammes of hydrargyrum oxydatum flavum. The daily dose was about from one to two milligrammes.

The effects in these cases also were uniformly good; appetite and the digestive functions soon improved in a marked manner; many expressed themselves decidedly as having a good, even a ravenous appetite. Within two or three weeks most of the men treated thus looked extremely well-nourished, and had good color. This all happened under circumstances not favorable to such rapid improvement of nutrition.

Ill effects from the administration of these doses of this form of mercury (it was given in over two hundred cases) were not observed in a single instance, not even where, as in cases of severe forms of angina, exceptionally, four to ten centigrammes were given in a few days.

Dr. Schaffer recommends the dose of one to two milligrammes, to which are added one to two grammes of sugar respectively, as a constituent, to be taken daily after a meal consisting of milk, eggs, or similar nitrogenized food, in all acute or chronic derangements of the alimentary tract, in typhoid fever, during the reconvalescence from surgical diseases, in phthisis, and in all cases where nutrition is impaired from any cause. He had occasion to observe a case of severe relapse after dysentery, with abscesses of the liver, in which the final recovery was seriously in question on account of the loss of appetite. The whole list of the stomachic remedies had been tried in vain, until finally the yellow powder caused a return of the appetite and brought about unmistakably decided improvement, a change for the better in the whole pathological process.

Thus, in many cases everything is gained for the patient, if only digestion be improved. According to Schaffer, much can be accomplished with one, two, or three centigrammes of hyd. oxyd., to be given during two or three weeks, and in some instances within a shorter period. Rarely will it be necessary to increase the dose. In chronic affections, pulmonary diseases, for instance, it is advisable to observe long pauses of three to six months before commencing a new term of administration of the remedy.

Schaffer gives the following formula: R. Hydrargyri oxydi flavi, 0.01; sacchari, 10.00. M. et divide in 8 partes æquales; D. et S., one powder daily—and he advises especially this dilution of one part of hydrargyrum with a thousand parts of sugar. I prefer, for convenience' sake, compressed tablets, which are prepared for me, and in which the sugar is added in the same proportion as in Schaffer's formula. Three tablets contain one milligramme of hydrargyrum. Tablets containing one whole milligramme with a whole gramme of sugar would be too large for any one to swallow without difficulty; while tablets containing only 0.0003 have the advantage of being of service in cases of children, for whom they may be pulverized if the little patients cannot swallow tablets.

I have only limited experience as yet with the yellow oxide of mercury, but in those cases of dyspepsia in which I prescribed the drug, especially in a case of pneumo-phthisis, I was very well satisfied that it merits all the praise Dr. Schaffer has bestowed upon it. I shall certainly give it another trial in all cases which I can bring under the heading of septic dyspepsia, or in which I wish to secure an aseptic state of the alimentary tract, be it as a curative or as a prophylactic measure.

Mercury is a means by which failing digestion and nutrition may almost certainly and promptly be improved. In very minute doses it is a most reliable antiseptic. Whatever the explanation of the excellent action of corrosive sublimate in diphtheria may be, one thing, it appears to me, is certain—it has a decidedly good and reliable effect on the septic dyspepsia associated with diphtheria. I have seen the unsurpassed good effects of sublimate given internally in some such cases.

Experience will have to decide whether the yellow oxide of mercury or the corrosive sublimate are to be preferred in the aseptic treatment of the alimentary tract. Perhaps it may matter very little which of the two is chosen, as long as the principle of their employment is established and the proper indications are fully known.

ON PARALYSES OF THE IRITIC MUSCLES—WITH TWO CASES.

By ALFRED HINDE, M.D.,

SURGEON EYE AND EAR DEPARTMENT CENTRAL DISPENSARY, CHICAGO, ILL.

CASE I.—*Dropsy of the sheath of the optic nerve—Paralysis of the radiating fibres of the iris of the right eye—Paralysis of the circular fibres of the iris, and the ciliary muscle of the left eye.*—Captain C. H——, late of H.M. 20th Light-Horse Regiment, and who has seen active service in the exciting times of Nana Sahib and the Indian mutiny, carrying now a sabre-wound scar in the left parietal region and a gun-shot scar of the left iliac region. He is fifty-four years of age, and was healthy when he arrived in the United States in 1882. Soon after his arrival he journeyed to the Canadian Northwest, where he stayed one year, on survey of the Canadian Pacific Railroad.

When thus occupied, and on account of the privations peculiar to frontier life, together with exposure to the extreme rigors of a Manitoban winter, he contracted rheumatism, and from this period he dates his present disease.

Patient was first seen January 3, 1884, and was then suffering from an acute bronchitis, engrafted upon emphysematous lungs, together with a displaced and slightly dilated heart.

The right pupil was myotic, diameter 2½ mm.; the left was widely dilated, diameter 6 mm.; both were immovable. The right pupil did not dilate when shaded from the light, neither did the left pupil contract on exposure to a bright light. The eyeball movements were perfect in both eyes, and there was no diplopia nor lateral deviation of the images on the prism test (the test distance was 12″, and the paralysis of accommodation was neutralized with +15 before the left eye).

Both eyeballs of natural appearance. The acuity of vision of the right eye was $\frac{20}{x}$, and rejected the weakest plus lens; read No. I. Snellen at 6″ to 26″, thus showing a normal accommodation and emmetropia. Vision with the left eye was $\frac{20}{x}$, and with +1.48 became $\frac{20}{xx}$; could read only No. V. Snellen at 12″, and with +15 read No I. S. at 12″. Here we had a paralysis of accommodation, with a recession of the far point, due to

a loss of the normal tone of the ciliary muscle of this eye, rather than a true [1] Hm $\frac{1}{14}$.

The left pupil had been steadily dilating for a period of nine months, yet the vision had not been sufficiently disturbed to cause distress, though now he was unable to continue his engineering work from imperfect tracings. Tension of both eye-balls alike and plus normal (?).

Ophthalmoscopic examination.—Left eye: media clear and fundus normal outside of disc; the upper two-thirds of the pupilla are normal, with clean-cut, healthy margin; physiological cup present, and occupies the central third of the disc. The lower part of the pupilla, limited at the margin of the physiological cup by a tolerably straight horizontal line, is occupied by a serous-looking projecting swelling of this portion of the nerve, over which the retinal vessels arch in their course from the retina to the centre of the disc. The adjoining retina retains its normal transparency and is not swollen.

The retinal veins are larger and darker than normal, and the arteria are natural.

The difference between the bottom of the cup and surface of the projecting portion of the disc = $\frac{1}{18}$; that between the normal margin of the disc and the surface of the swollen portion = $\frac{1}{36}$. Thus the lower portion of the disc reached forward $\frac{1}{36}$ beyond the margin of the remaining part.

Through the small right pupil the disc was seen to be normal; same physiological cup but no swelling; veins, if anything, slightly larger than natural.

February 5, 1884.—Has fully recovered from his acute sickness, but the condition of both eyes is the same.

A solution of eserine was instilled into the left eye, which resulted in an aching of the eye-ball, and the pupil contracted in twenty minutes from a diameter of 6 mm. to 2 mm., and his vision with this eye fell off to $\frac{20}{lxxx}$, and required $-9\frac{1}{2}$ to restore it to $\frac{20}{xx}$.

Into the right eye a solution of homatropine was instilled three times at intervals of a few minutes, and twenty minutes later from a diameter of $2\frac{1}{2}$ mm. the pupil had dilated evenly to a diameter of 6 mm., and there were no evidences of a previous iritis.

The general condition of the patient was attended to, and bi-weekly instillations of eserine were more or less irregularly used in the left eye during a period of three succeeding months. On re-testing, the vision of this eye was $\frac{20}{xx}$, and read No. I. Snellen momentarily at 15″ to 19″, and with $+18\frac{1}{2}$ No. I. Snellen steadily at 8″ to 23″. On first using the eserine, the pupil fully dilated in forty-eight hours, but toward the last the action of the remedy lasted three full days; the ocular subjective sensations, at first benumbed, after treatment became natural. The far point was restored to its normal position, and there had been some gain in the accommodative power.

It is now fourteen months since the patient came under observation, and his present status is as follows:

Left eye-ball in appearance and movements same as a year ago, diameter of pupil 6 mm., iris immovable, visual acuity $\frac{20}{xx}$, and reads No. II. Snellen at 20″ to 24″, and with +15 reads No. I. Snellen at $7\frac{1}{2}$″ to $17\frac{1}{2}$″. The slight gain under treatment has been lost, but we may presume that the worst has been reached with this eye, for no other paralyses have occurred. The iris responds to eserine as before.

Right eye-ball perfect in all its movements, the same myosis, diameter of pupil $2\frac{1}{2}$ mm., and the same immobility of the pupil as a year ago, and the iris, though free, does not dilate when shaded. It responds to homatropia as before. The acuity of vision is $\frac{20}{xx}$, and he reads No. I. Snellen at 6″ to 21″ easily, thus showing a normal accommodation.

The right disk has a serous-like projection of its lower portion in all its characters similar to the one already described in the left fundus. This condition was first noticed about six months ago, but then it was only of slight extent, yet advancing, and now it is equal to the swelling in the left pupilla. It would seem that we had reached the full extent of the disease of this eye, for there has not occurred any paralysis of the third nerve-fibres supplied to the sphincter pupillæ, or to the ciliary muscle during the fourteen months' observation.

In this interesting case, therefore, was present a paralysis of the radiating fibres of the right iris, together with a paralysis of the sphincter pupillæ, and the ciliary muscle of the left eye. Owing to the multiplicity of diseased conditions of our patient, it is impossible to justly compute the etiological factor of each in the production of the intra-ocular paralyses.

From the appearance of the discs, we believe that there was a dropsy of the optic nerve-sheath, and that the exudation was insufficient to surround and compress the entire optic nerve. It is also probable that there was a localized rheumatic inflammation of the left optic nerve-sheath when the patient was first seen, that later extended to the right side, resulting there in an exudation into the intervaginal space of sheath of the right optic nerve (there is a case of "Dropsy of the Sheath of the Optic Nerve" reported in *Klinische Monatsblätter für Augenheilkunde*, August, 1865. See reference to same, Royal London Ophthalmic Hospital Reports, vol. v., p. 234).

Our patient was free from all head symptoms of disease. The fact that his first evidence of "catching cold," to which he was prone on the least exposure, was always shown by a profuse watery diarrhœa, followed by watery and bitter-tasting emesis, together with oppressed breathing, would seem to indicate that the entire sympathetic system was easily unstrung, resulting in a dilatation of the blood-vessels and an exudation of their fluid contents. The diarrhœa lasted usually about twenty-four hours, and at this period he, for the first time, would notice evidences of nasal and pharyngeal catarrh.

Of other appearances present, the right palpebral fissure was the smaller, and this appeared to be due to a slight retraction of the right eyeball. The temperature was the same on both sides.

Considering our patient an excellent example for testing the relative influence upon the pupil of mere paralysis of one iritic muscle, and again of paralysis of the same muscle, together with spasm of the opposing muscle, we, after explanation of the details of our wish, were graciously permitted by our intelligent patient to carry out the following investigations:

With a desire to see the influence of spasm of the sphincter of the right pupil upon the diameter of the latter, a drop of a solution of eserine was instilled into the right eye. Aching commenced in five minutes, became extreme, and at the end of thirty minutes the pupil, from a diameter of $2\frac{1}{2}$ mm., had contracted to one of 1 mm., thus demonstrating, in this case at least, that a spastic contraction of the sphincter pupillæ results in a greater degree of myosis than a mere paralysis of the radiating fibres of the iris can alone accomplish.

The acuity of vision = $>\frac{20}{xxx}$ (deciphers $\frac{5}{6}$ of the types), and with -30 V. = $\frac{20}{xx}$. He could now read No. I. Snellen, at 3″. Thus a spasm of the ciliary muscle was associated with a spasm of the sphincter pupilla. The aching was soon overcome by repeated instillations of a solution of homatropine.

To ascertain the effect of spasm of the radiating fibres of the iris upon the diameter of the left pupil, a solution of homatropia was instilled three times at intervals of a few minutes into the left eye. Aching resulted in five minutes, though not severe, and at the end of forty-five minutes the pupil, from a diameter of 6 mm., had dilated to one of 8 mm., thus demonstrating that a spasmodic contraction of the radiating fibres of the iris results in a greater mydriasis than a mere paralysis of the sphincter pupillæ can produce.

The acuity of vision = $\frac{20}{xx}$, and with + 74 was slightly

[1] Donders (p. 600) considers the normal tone of the ciliary muscle of the emmetropic eye equal to Hm $\frac{1}{400}$, developed by atropia-paralysis.

more distinct. He could read only No. X. Snellen with the nearest point at 15″.

If the above be the rule, it would appear that on the one hand we must not expect to find an extreme condition of myosis in uncomplicated paralysis of the radiating fibres of the iris, and, on the other hand, we are not likely to find an extreme mydriasis in simple paralysis of the sphincter of the pupil.

If these conclusions can be safely applied in practice, their bearing on the recognition of cases of paralyses of the iritic muscles will be obvious, especially in bilateral examples of the same.

One more observation on the pupillary diameters may be made from the following: The diameter of the right myotic pupil in a condition of rest was 2½ mm., and under the action of a solution of homatropine (sufficiently strong and used often enough to get the full effect) became dilated to a diameter of 6 mm. In this eye we had a paralysis of the radiating fibres and an irritation of the same, together with a paralysis of the circular fibres of the iris, which did not result in as great a mydriasis as homatropia produced in the left eye where the radiating fibres where normal, and the pupil became a diameter of 8 mm. On account of greater action of the remedy on the left eye, an irritation of the supposed normal radiating fibres may be presumed to be the sole cause of the widely dilated pupil; whereas in the right iris, with the paralysis of the radiating fibres, the remedy failed to exert so marked an influence on their construction, or its paralyzing effect on the sphincter was less pronounced.

Again, the diameter of the left pupil in a condition of quiet was 6 mm., and under the full effect of eserine became one of a diameter of 2 mm. In this eye the paralyzed sphincter could not be made to contract as markedly as the healthy circular fibres of the right eye did under the same conditions, for the right pupil under eserine contracted from a diameter of 2½ mm. to one of 1 mm. Eserine would seem to act solely upon the healthy sphincter pupillæ in this eye (right), and resulted in much more marked contraction than it could possibly produce on the paralytic fibres of the sphincter of the pupil of the left eye.

It has been already demonstrated, in this case at least, that spasm of a healthy iritic muscle results in a greater effect upon the pupil than a mere paralysis of the opposing muscle can alone accomplish. Also, it would appear proven from these later observations that a spasm of a previously paralyzed muscle is very much feebler than a spasmodic contraction of a perfectly healthy muscle. To the physiologists are relegated the above observations for further explanation or correction.

Mr. Jonathan Hutchinson, in a paper entitled '"Clinical Notes on Paralyses of the Ocular Branches of the Cervical Sympathetic Nerve," enumerates the following chief symptoms attending these cases: "1. Contraction of the pupil [the myosis even in a young person is not of such degree as to attract attention, the pupil is of the size which it would naturally be in a good light]; 2, immobility of the pupil [this is almost absolute, the pupil neither dilates when shaded nor contracts much further when exposed to light]; 3, retraction of the globe in the orbit; 4, narrowing of the palpebral aperture; 5, alteration (increase) of temperature in the parts affected; 6, dilatation of arteries; 7, a slight difficulty in vision observed by the patient both for near and distant objects, and especially when the light is bad."

He continues: "The cases which have come under my observation have been very various in respect to their cause and complication. Sometimes it is met with as the only symptom of disease of the nervous system present, at others I have found it in conjunction with paralysis of one or several of the cranial nerves, more especially the third, fifth, or sixth. In other cases it occurs from injuries of the spinal cord or to the roots of the brachial plexus. The symptoms present vary considerably in connection with one or other of these complications. Thus, if there be paralysis of the third nerve at the same time, the pupil will not be contracted, but will be absolutely motionless in a state of moderate dilatation."

"Cases of paralysis of the radiating fibres of the iris are, I feel certain, frequently overlooked, owing to our habitually examining our patients in a good light. When well exposed to light the pupil of the sound eye contracts to the same size as that of the other, and there is no difference to be observed. It is only when the patient is taken into the shade, and the pupil of the sound eye dilates widely, while that of the other remains contracted as before, that our attention is arrested. If we see our patient for the first time in a dull light, the suspicion which crosses the mind first is certain to be that we have to do with a case of paralysis of the third nerve, and mydriasis as the result, but on bringing him to the light we find the supposed mydriasis disappear. I have several times made the two mistakes to which I refer, and have seen them made also by others."

"Inequality of the pupils, the smaller one being the fixed one, is then the cardinal symptom of paralysis of the sympathetic, just as inequality of pupils with the larger one fixed is the cardinal symptom of paralysis of the third, as far as the supply of the iris is concerned."

Among other cases complicated with injuries, syphilis, amaurosis, etc., he records the following case:

"Case I. *Paralysis of radiating fibres of the iris without known cause, and without other complications.*"—Patient, a clerk, aged thirty-four; health good; complained of failing sight in left eye for two months past, together with pain and mistiness; had noticed that right pupil was three times the size of the left: no other ocular paralysis, and he persisted that his left eye was defective; in strong light the right pupil contracted to same size as the other, which was myotic and immovable when shaded; visual acuity, L. E., $\frac{20}{xxx}$; and he could read the smallest type "with some difficulty at 12″, but not either nearer or farther off." "R. E. vision, $\frac{20}{xx}$, and read smallest type easily at 8″ to 14″." With the ophthalmoscope nothing abnormal was detected. "There was no history of syphilis and no other nerve symptom." Iodide of potassium, nux vomica, with vegetable bitters, were given without benefit. No difference of temperature was noticeable on the two sides, and "no proof that any other part of the sympathetic is involved excepting that which supplies the radiating fibres of the iris. I have tried the effects of calabar bean, and, as expected, found that it contracted the myopic pupil very greatly. Under its influence the pupil was reduced to the size of a pin's head, thus affording proof that in spasmodic myosis the contraction is far greater than in the paralytic form."

One year later ("Royal Ophthalmic Hospital Reports," vol. vi., p. 142), Hutchinson, referring to the above case, says: "in which complete paralysis of the radiating fibres of the iris occurred without complication and without any known cause. In that case failure of the function of accommodation gradually supervened and became complete," and fifteen months after the beginning of his disease no other ocular paralysis had occurred, and the other eye was not affected, the patient being in good health. He states that he has further seen two similar cases and records one: A healthy, married man, aged thirty-five, used to office work; no syphilis; could not see clearly with left eye, and had shooting pain in and around it, though not severe; eyeball normal, but pupil immovable in shade while the right dilated; sight good for distance, though objects hazy; could read No. IV. Snellen at 4′, but not nearer; with +15 he read No. I. easily at 12″. "The right eye perfect and its pupil acted well."

Thus was present "paralysis of the radiating fibres of the iris and of the ciliary muscle without apparent cause and without other complication." This patient was very sensitive to weather changes and had neuralgia.

[1] R. O. H. Reports, vol. v., pp. 135–148.

These two cases are different from my own in the fact that in both paralysis of the ciliary muscle followed paralysis of the radiating fibres of the iris, whereas, though I have observed my patient fourteen months, no paralysis of accommodation has resulted in the myopic right eye.

Hutchinson considers treatment of little avail, but writes: "The worst result to be feared is, however, a complete paralysis of the ciliary muscle and of the dilating power of the iris." He further writes (Royal Ophthalmic Hospital Reports, vol. v., p. 138): "The converse of this class of cases is met with in paralytic mydriasis without other complications. Mydriasis without other symptoms of impairment of the third nerve is rare, but good examples do occasionally happen. I have now under observation in the London Hospital an instance of it. The man has neither strabismus, diplopia, ptosis, nor paralysis of accommodation, but simply wide dilatation of the pupil. Mr. Dixon has at present a young woman attending his clinic at Moorfields with a precisely similar state of things."

Donders, at page 592 writes: "Uncomplicated paralysis of accommodation has only one objective symptom; dilatation and immobility of the pupil. The dilatation is not considerable, for even with complete paralysis a wider pupil than the normal in the dark is not to be expected. Nevertheless in complete paralysis not a trace of either accommodation or of reflex movement is to be seen. But I may add that these cases are extremely rare. Further, the connection between paralysis of the pupil and of accommodation cannot be called absolute; once I found satisfactory accommodation still coexistent with absolute immobility of the pupil. In one instance, too, paralysis of accommodation disappeared [1] without a return of the mobility of the pupil, and on the other hand, with perfect or almost perfect loss of accommodation the motion of the pupil may be but little disturbed."

I have no notice of an example of uncomplicated paralytic mydriasis, but in a hurried search the following other instance has been found (Royal London Ophthalmic Hospital Reports, vol. iv., p. 117): "Mydriasis (dependent on general debility?)." The patient, a girl aged sixteen, of weak health and sight, could read with her left eye type No. I. at 4″, and the diameter of the pupil was 3‴ (=7 mm.). Under the action of calabar bean for thirty minutes the near-point approached the eye to 1½″, and the pupil contracted to 1½‴ (=3½ mm.).

In the left eye of my own patient there was a paralysis of the circular fibres of the iris, together with a paralysis of the ciliary muscle, but without further implication of the third nerve. As an example of intraocular paralysis of the third nerve the following case is interesting; the sixth nerve was alone involved in the fellow-eye.

Case II. *Paralysis of the sphincter pupillæ and the ciliary muscle of the left eye—Paralysis of the external rectus muscle of the right eye.*—The above conditions were present and without change for a period of six and one-half years. The patient had worked in "lead works" for three and one-half years previously, and when first attacked the muscles of the right side of the face and of the left side of the body were tremulous and weak, so much so that he could not hold anything with his left hand, from inability to clutch the object, the left lower extremity and left knee-joint were weak, and the temperature of the left side was lower than that of the right. His first symptoms were an obstinate constipation and much colic. Though paralytic, and internal strabismus was present in the right eye, he could read with it No. I. Snellen at 7½″ to 15″ without glasses. The diameter of the right pupil was 3½ mm.—the patient's age was forty-one years, and its small size may be thus accounted for—and it responded readily to direct light and also with the other retina.

With the mydriatic left eye he could read only No. XIII. Snellen at 22″ without glasses, yet with +12 he read readily No. I. Snellen at 12″. The diameter of the left pupil was 8 mm., which, after the instillation of eserine, had a diameter of 3½ mm. in forty-five minutes, and could read No. I. Snellen at 7½″, thus in both the latter conditions this eye had approached that of the normal right eye. The distant vision of the left eye was now reduced to $\frac{20}{cxx}$, and required a −12 lens to bring it up to $\frac{20}{xxx}$. The eye had a normal direction and normal movements. The distant vision of both eyes was alike, viz., $\frac{20}{xl}$, and could not be raised above $\frac{20}{xxx}$ with any glass, but with +7 4 it reached this amount. During the effort at near vision with the mydriatic left eye I observed that the near point of the right eye approached the same, becoming nearer than my previous test showed, and thus was suggested the possibility of voluntary spasm of the right ciliary muscle due to the impulse at near vision with the left eye.

I observed the above case during a period of two months, and though treatment, both local and constitutional, was carried out, no improvement occurred and the patient disappeared.

This patient had previously been under the care of Dr. Kipp, of Newark, N. J., and had been seen by Dr. Knapp, of New York, but he said he had not received any benefit whatever from treatment.

The etiology of these paralyses is undefined, more especially in the apparently uncomplicated cases. Neuralgia is mentioned in one of Hutchinson's cases. Syphilis, though a common cause, is excluded in all the cases referred to in these notes. In one of our own patients rheumatism was an important factor. In the other lead-poisoning was undoubtedly the cause. Donders, when discussing the causation of paralysis of accommodation (at page 596) writes: "Experience shows that in sudden changes of temperature, particularly on exposure to storms or draughts" paralysis occurs. "Such cases are called rheumatic, and are referred by some to an inflammatory affection of the nerve-sheath."

Wells (4th edition, p. 293) writes: "Idiopathic mydriasis is not infrequently due to rheumatic origin, the patient having been exposed to cold and wet, and it is in such cases probably caused by rheumatic inflammation of the nerve-sheaths." Heart disease is frequently an associated affection. In the production of paralysis of the intraocular muscles injuries to, and diseases of, the cerebro-spinal system play, most probably, the most important part.

Treatment, as shown in the foregoing cases, is usually of little avail.

16 Laflin Street, Chicago, Ill.

[1] In our Case I. of these notes the accommodation was more or less completely restored under treatment, though only temporarily so, yet the pupil remained perfectly motionless throughout.

The Prevention of Cholera.—Dr. William M. Smith, Secretary of the Medical Society of the State of New York, has received the following communication from James D. Porter, Assistant Secretary of the Department of State, Washington: "Sir, I have to acknowledge the receipt of your letter of the 18th of February last, transmitting a copy of a resolution adopted at a meeting of the Medical Society of New York, together with certain remarks of S. Oakley Vander Poel, M.D., relating to the adoption of measures to prevent the importation of cholera into the United States. In reply I have to say that prompt measures are being adopted to secure the examination by medical officers of all vessels, passengers, etc., bound for the United States from infected districts, and no effort will be spared to prevent the disease from reaching our shores."

On a Bean in the Trachea.—Referring to curious expressions which get into medical journals, we observe that an English contemporary speaks of "Dr. Ladangi on a Bean in the Trachea." The doctor's position must have been attended with considerable discomfort.

Progress of Medical Science.

Tuberculosis of the Œsophagus.—It has been asserted by some authorities that the œsophagus is never the seat of tubercular lesions, but this is manifestly erroneous, although the affection is certainly very rare. In a study of the subject made by Dr. Luigi Mazzotti, and published in the *Rivista Clinica* for January, 1885, a reprint of which we have received, several cases are reported, three of them being personal observations. The author states that tubercular lesions of the œsophagus are of two kinds. In some cases pulmonary cavities or caseous lymphatic glands open into the œsophagus, forming one or more fistulous openings surrounded by an area of hyperæmia or of simple inflammation of the mucous membrane, or there may be a tuberculous ulceration due to local infection. In other cases there are tuberculous ulcers unassociated with perforation from without, but these never exist in the œsophagus alone, but are always associated with tuberculosis of other organs. They are usually few in number, never exceeding five or six, and are situated most frequently in the lower third of the tube. The ulcers are usually superficial and small, of a regular, somewhat oval shape, and with a smooth reddish base. The surrounding mucous membrane is somewhat hyperæmic, and contains disseminated gray or yellow granules of varying size. In the cases seen by the author, tubercle bacilli were found in considerable numbers. The ulcers, as a rule, give rise to no symptoms, though sometimes there are pains in the sternal region and in the back, and difficulty in deglutition, which latter may even be so marked as to cause death from inanition. In such cases there is a stricture of the canal in addition to the ulcerative process. Whenever, in a tuberculous subject, there is dysphagia and the sound detects a narrowing in the lower portion of the tube, a diagnosis of tubercular ulceration may be safely made. Treatment of this affection narrows itself to an attempt to prevent further contraction of the stricture in case the symptoms of dysphagia become urgent.

Nervous Colic.—Dr. Shershevski reports a number of cases of colic which seemed to be due to a neurasthenia localized in the nervous sphere of the intestinal canal. They were all in intelligent individuals whose work was chiefly with the head. These persons suffer habitually from constipation, with abdominal distention and burning eructations, but without loss of appetite. From time to time, under the influence of prolonged intellectual work or of mental emotions, an aggravation of this condition occurs, with the following symptoms: Excessive meteorism with or without a discharge of gas from the bowel, superficial panting respiration, cyanosis, pains in the neighborhood of the liver or in the umbilical region, or shifting, or feeling of weight in the lower part of the abdomen and severe tenesmus. The attacks subside after some days with the occurrence of copious evacuations. Shortly before their onset the fæces become flattened, as if there were an intestinal stricture. The author attributes these symptoms to a lesion of the nervous system producing an intestinal spasm located in the circular fibres of the muscular coat. This theory of the etiology would seem to Dr. Shershevski to be demonstrated by the action of the remedies employed. For, while purgatives increase the pain and constipation, opium and belladonna reduce the meteorism and cure the attacks.—*Lyon Médical*, March 1, 1885.

Vagus Pneumonia.—The Vienna correspondent of the London *Lancet* (March 7, 1885) writes as follows concerning vagus pneumonia: "The changes in the lungs caused by cutting through the vagus nerves have formed, since the time of Valsalva, the subject of very deep research. All animals whose vagi have been divided in the throat perish sooner or later. Most of them die of broncho-pneumonia. Traube is of opinion that this vagus pneumonia is caused by the penetration of mucus and of food matters into the trachea. Schiff, however, gave the following explanation: The vagus is the nerve which supplies the muscles of the vessels of the lung; if it is severed, paralysis of the muscles with hyperæmia and inflammation occur. In order to decide the controversy, only the branches of the vagus which proceed to the lungs should be cut through, whereas the recurrent laryngeal nerves must remain intact. Dr. Gärtner and Dr. Amrüs have, in Professor Stricker's laboratory, cut through the vagus below the recurrents after two methods. According to the first, they divide the recurrent laryngeal in the neck, and connect it with the vagus at the throat, where it heals up, after which they cut through the vagus below this spot. A dog which was thus operated on on both sides died after sixteen days, and showed no broncho-pneumonia at the autopsy. The second method is more exact. The pleural cavity is opened, and then resection of the vagus is performed under antiseptic precautions. The branches proceeding to the heart and to the larynx remain intact, and only those branches are divided which supply the lung and stomach. A dog in which, on the thirtieth day after the operation, a gastric fistula was produced, perished on the forty-sixth day, obviously owing to the latter operation. At the autopsy no pneumonia could be detected; the lungs were pale, without the slightest infiltration. Consequently the question of vagus pneumonia is definitely settled according to the views of Traube."

Excision of the Cæcum for Epithelioma.—Mr. W. Whitehead reports a case in which he excised the whole of the cæcum for epithelioma. The patient was a man aged thirty-eight, who had suffered, for eighteen weeks before admission into the Manchester Infirmary, from diarrhœa and pain in the right lumbar region. On examination there was found a mass in the right lumbar region, about four and a half inches long by three inches broad. The tumor was freely movable, and the clinical diagnosis made was, a tumor of the colon in the vicinity of the cæcum, probably epithelioma. It was decided to remove the whole disease by an incision along the outer border of the rectus muscle, in preference to that for lumbar colotomy, by this means affording more room for exploratory purposes. The operation was performed most successfully. The whole mass was taken away, entailing the removal of the last two inches of the ileum, the cæcum with the vermiform appendage, and the greater part of the ascending colon. The cut end of the small intestine was stitched to the lower edge of the wound, and the colon was stitched to the upper edge. The remaining portion of the wound was next brought together by strong silver wire passed through the skin, muscle, and peritoneum, the surface of the wound being dressed with iodoform. The patient did very well for about ten days after the operation, but peritonitis then set in, and death took place on the thirteenth day. The author remarks that the patient did not die from the immediate effects of the operation, and the *post-mortem* examination showed that the whole disease was removed. The operation is serious, and should only be undertaken in cases where there is hope of giving permanent relief; but in cases where there is only a chance of relieving symptoms temporarily, the operation of colotomy should be performed.—*British Medical Journal.*

Treatment of Tetanus.—The following is a summary of the treatment advocated by Professor Verneuil for this disease (*Revue Médicale*, February 28, 1885): 1, Complete immobilization of the patient, obtained by fastening him firmly in a large gutter splint for the body and limbs; 2, the maintenance of an elevated and constant temperature, with light diaphoresis, by enveloping the patient in a thick covering of cotton-wool; 3, uninterrupted sleep, obtained by a chloral intoxication, maintained constantly for upward of three weeks.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, April 25, 1885.

ETHICS OF PLACEBOS.

THE physician has a duty, not only to his patient, but to society. He has no right, for example, to prescribe for his patient unlawful things, that he may get well. An invalid saint is better than a healthy villain as a factor in society. This principle, when laid down in a general way, will be freely enough accepted. It would be well if it were brought to bear a little more closely upon everyday work; for the physician is very apt to think that his duty begins and ends with simply treating the illness of his patient.

The doctor also owes something to himself in the matter of morals. He ought to treat his patient in the most skilful way possible; yet he need not to make of himself a liar, or a thief, as a therapeutic "pick-up" for his patient. Something in this direction, to be sure, does have to be indulged in at times. A doctor is in duty bound, upon certain occasions, to tell a lie and deceive his patient, and he is more than justified in so doing. For it is better and more humane to preserve life and happiness than to refrain from telling an inconsequential untruth.

We feel strongly opposed, however, to erecting such a permissive measure into a canonical practice. And this we regret to observe is done by Dr. Cathell in his somewhat worldly-minded book "The Physician Himself." "A placebo or tentative remedy," says this author, "should, as a rule, be small and easy to take. A very good form is prepared thus: Purchase a pound box of No. 35 unmedicated homœopathic globules, which cost but 35 cents, and immerse one-half of them in fluid extract of belladonna, and the other half in compound tincture of iodine for twenty minutes," etc. . . .

"You will not only find that your placebos amuse and satisfy people, but you will often be surprised to hear that some full-of-faith placebo-takers are chanting your praise, and are actually willing to swear that they are cured of one or another awful thing by them; cheated into a feeling of health by globules, or teaspoonful doses of flavored water, or licorice powder, as if by a charm."

"But," continues our casuistical adviser, "never send a patient to the drug store with a prescription for bread pills. It is not right to make any one pay for bogus medicines; besides, if, from among all the articles in the Pharmacopœia you cannot devise some trifling placebo that is more plausible than bread pills, you must have an unusual paucity of resources. Moreover, were a patient to discover that he had been paying for such a thoroughly insipid cheat, he would naturally feel victimized and indignant."

It is hard enough for a physician to withstand the constant temptations to indulge in humbug, which fools set forth to him. So hard is it indeed that an honest physician is probably one of the honestest men in the world. We strongly deprecate, therefore, the adoption of the placebo into everyday practice. It must encourage the physician to indulge in what Dr. Cathell characterizes later as an "insipid cheat;" it must relax a little the moral fibre and inculcate a distrust in the resources of medical art. Prescribing placebos is rarely necessary, if the physician is intelligent enough to get to the bottom of his patient's trouble, mental, or physical, and placebos are the handmaids generally of indecision and therapeutic and diagnostic ignorance. The attempt to draw a line between the morality of writing for a bread pill and that of giving a bottle of sugar-globules direct, brings out one of the finest points in casuistry which has ever been discussed. In the one case the act is an "insipid cheat;" in the other—well the adjective is to be omitted.

We have read Dr. Cathell's work with admiration for the knowledge of human nature which he shows, and in general the tact and good sense displayed in his suggestions. But he gives us a somewhat disheartening picture of the frailties of patients and leaves one with a dismal impression that alertness in recognizing these frailties is rather more important than sturdy honesty, earnest purpose, and hard work. We advocate the three latter principles. They will bring success also, and a more satisfactory if less early one.

THE SIGNS OF DEATH.

THE *Cleveland Leader* gives its editorial endorsement of the story of a boy living in Freeport, O., who to all appearances died, and was in due time prepared for burial. "On the day of the funeral, just before the encoffined boy was to be lowered into his grave, the casket was opened at the urgent request of the mother. A slight moisture attracted the attention of the bystanders, and the body was promptly removed to a house near at hand. An effort was made to produce resuscitation, and after several hours' labor the lad was restored to consciousness, and is now in a fair way to recover." We are somewhat skeptical of the truth of this story and must positively deny the *Leader's* statement that "similar cases are constantly occurring all over the country." With the rarest possible exceptions, death but too strongly and swiftly puts a mark upon his victim.

The *Leader* calls upon medical science to pay more attention to this subject. The fact is that the subject has been studied until the signs of death are multiplied to a degree beyond the capacity of an ordinary memory to retain. They may be classified, however, under nine heads.

First.—The entire and continuous cessation of the heart's action. This is the best and most certain of single tests. Even in cases where vitality is reduced to the very lowest limits, the sounds of the heart can almost always still be detected. In order to detect any action of the heart, there have been several minor tests suggested.

Such are the tying a ligature round the finger, the application of wet cups, the oxidization of brightly polished steel needles thrust into the muscles; the cutting down upon the temporal artery which after death is pale, yellow, and empty, the subcutaneous injection of a little ammonia, which, *ante-mortem*, sets up a port-wine congestion.

Second.—The entire and continuous cessation of breathing. This is tested by holding a cold mirror before the mouth, by suspending a feather near the mouth or nose, and by placing a glass of water or mercury on the chest, and watching for any movement on the surface of the liquid. None of these tests are very absolute, though ordinarily they are sufficient. It is to be remembered also that while the heart may cease to beat for a quarter of an hour or more, and then resume action, respiration may be suspended for a period three or four times as long.

Third.—Insensibility and loss of power to move. This is, of course, a test of minor value, as a condition of insensibility and immobility exists in asphyxia, syncope, apoplexy, trance, and cateleptic states.

Fourth.—Tidy classifies together certain minor signs of death. These are: the application of heat so as to raise a blister. If the fluid in the vesicle is rich in albumen, if the cutis vere underneath is reddened and surrounded by a deeply injected red line, the part is alive.

If a caustic be applied to the skin of a dead person there is no eschar, or else it is yellow and transparent instead of being black or reddish brown. The facies Hippocratica is present in many cases just before and after death, but not in all, and it is absent after sudden death. Carrière's test is a familiar one: If the hand after death be examined by transmitted light, it appears marble-like and opaque, while before death it is transparent and rosy.

Fifth.—Changes in and about the eye. The iris dilates, the light-reflex is lost, and the muscle is flaccid. The cornea loses its sensibility and transparency. The conjunctivæ show gray cloudy discolorations, due to films of mucus; the eyeball loses its tonicity and elasticity; the fundus is of a yellowish white color, and there is a beaded condition of the veins due to the presence of bubbles of the air (pneumatosis of the veins).

Sixth.—Changes in the temperature of the body. After, in some cases, a preliminary rise, the temperature of the body gradually falls on an average at about the rate of 1° F. an hour.

Seventh.—Changes in the muscles of the body. These changes are divided into three stages: that of flaccidity, which commonly lasts about three hours; that of muscular rigidity, or *rigor mortis*, a condition first suggested by Louis as a test of death, and one which lasts in winter from twenty-four to thirty-six hours, and in summer from thirty-six to forty-eight hours. The third stage is that of putrefactive change. The formation of adipocere and the desiccation and mummification of bodies are late signs of death which are of secondary interest and importance.

It is certain from the above that science has supplied a sufficient number of signs of death, and he is a very ignorant and culpable man who does not know enough about them to guard against the possibility of burial alive.

As Tidy says, "Whatever *may* have happened, modern stories of premature burial in England belong to the domain of the novelist rather than the scientist. Further, the signs of death are, for the most part, as certain and as definite after a few hours' suspension of the vital functions as they are after many days."

THE CONDITION OF GENERAL GRANT.

THE physical condition of General Grant has markedly improved during the past week. There is no authority for the statement that his physicians at any time prognosticated speedy death, or did not give the most encouraging reports of the patient's progress. In fact, it has been charged that the physicians were suppressing all reference to graver symptoms.

The bulletins which have been issued at the request of the family of General Grant, and in answer to the incessant demands of the press, have been simply bare statements of the exact conditions at the time, without any theories or comments. The medical attendants are consequently in no sense responsible for the mass of sensational rumors that come from non-professional sources and fill the newspapers.

The medical staff has always maintained that the amount of the general constitutional depression was out of all proportion to the extent of the local disease; that the latter would not of itself be the cause of death unless by the accidental erosion of a large artery, or possible strangulation from the sudden separation of the slough. Both these contingencies were guarded against by every possible precaution which could be taken. In the meantime, as the result of the most careful topical and general treatment, the bodily strength of the patient was nurtured, his pain assuaged, his sleep secured, and in this way his life has been prolonged.

At one time only did death seem imminent from general exhaustion and threatened heart failure, and but for timely assistance would probably have occurred. On no other occasion has there been any cause for alarm. The General has never been in any danger from choking, and the only hemorrhage which occurred was of slight extent and ceased of itself.

General Grant is now stronger, and his physicians are neither dumbfounded nor surprised. It was what might have been expected, and all treatment has been directed to that end. The slough has nearly entirely separated from the throat, and so far a source of immediate danger has been removed, but the throat disease is still there, although for the present it is apparently quiescent. There is certainly nothing in all this to prove any error in diagnosis or prognosis. Nor has there been the slightest disagreement in regard to the management of the case.

The microscopic examination of the specimen removed from General Grant's throat has declared the disease to be epithelioma. The representation of the appearances has been widely published, has challenged every criticism from scientific sources, and not a microscopist in the land has as yet offered a protest to the conclusion. But epithelioma, barring accidents from complications, is not a very rapidly progressive disease. It may continue for months, slowly eating its way into surrounding tissues without of itself killing the patient.

It must not be supposed that General Grant's physicians

have neglected to take into account every possible source of error, and have not treated the case accordingly. Unfortunately the progress of the throat trouble under well-recognized methods of treatment has thus far not been such as would lead them to believe that the microscope was in error in confirming the original diagnosis.

THE PRESENTATION OF DR. BARKER'S PORTRAIT.

The presentation of the portrait of Dr. Fordyce Barker to the New York Academy of Medicine was a graceful recognition of the distinguished services of the honored ex-President of that body. The eloquent address of Dr. Markoe leaves nothing to be said concerning the motives which actuated the donors, or of the due appreciation of the gift by the recipients. The occasion was one long to be remembered in the medical history of New York. Few medical men in this country have won for themselves, by dint of hard, faithful, and conscientious work as high a position in their profession, as has the venerable ex-president; but none, despite much petty opposition, has vindicated his course more consistently or triumphantly. He has been the recipient of many honors both here and abroad, but we venture to say that none bear with them a greater significance in his own home, and among those with whom, for a long and eventful life, he has worked, than this latest tribute. In one sense it is the refinement of the gold after having passed through the fire.

It is well known and widely appreciated, that to the personal efforts of Dr. Barker the Academy of Medicine owes much of its present prosperity. For many years its president, he has labored long and faithfully in its best interests, and his efforts have been crowned with a success as remarkable as it has been gratifying. During all the recent regretful troubles in that body, and often with a sacrifice of personal conviction, he has, in his capacity as presiding officer, generously and impartially calmed heated discussion and carried the Academy dignifiedly through many a stormy debate. Retiring from its highest office with the love of his friends and the respect of those of different opinions, his crowning honor has been a lasting place in the memories of those of his dearly cherished medical household.

RELIGIOUS CONSISTENCY.

Some months ago we took occasion to commend some very sensible words from the editorial pen of the Rev. Dr. Buckley in the *Christian Advocate*. In the article referred to he condemned the American practice of self-medication with patent remedies. He declared the physician to be the one and the only one to be consulted when our physical frames were disordered. Therefore he excluded all advertisements of patent medicines from the columns of his paper. We commended his position, especially because it was a somewhat unique one for the editor of a religious journal to take. We took him into full fellowship, so to speak. Recent events seem to indicate that in so doing we acted prematurely. We should have required him to show the permanency of his faith by the continuance of his works.

In a recent issue of the *Advocate*, in a corner of one of the last pages, are extolled the virtues of a "cough balsam" which "heals irritated throats, relieves the cough, and helps the throat and lungs to resist the influence of climate so severe at this time of year. It is used by the most prominent people. Take no other, you would not be satisfied," etc., etc. On smaller banners in this therapeutic heraldry are emblazoned the virtues of some "sick headache pills," and an "elixir for all aches and pains." *Mirabile dictu.* In the twinkling of an eye is the problem of the ages thus easily solved. The deadly upas poison distilling from the above trio of remedies is, to a certain extent, neutralized by neighboring advertisements. Above, the sweet notes of a church organ remind us of fairer scenes. At one side the siren voice of the elixir is hushed by the awe-inspiring words of Joseph Cook's lectures. It was judicious to place the advertisement where it would do the least harm.

In all seriousness, we are sorry to note this seeming fall from grace on the part of our Methodist brother. We say seeming fall, because there may be extenuating circumstances in the case of the elixir, the pills, and the balsam which do not obtain with other nostrums. We fear that the standard of the *Advocate* has been somewhat relaxed during these hard times, and that the fingers of Mammon are endeavoring to grip themselves upon its advertising columns.

That sick people need a physician—one trained in his art, and not patent remedies is the spirit—of that religious system the *Advocate* defends. Miracles in the olden time bore the impress of Divinity. The healing art of to-day is seen in its highest consummation in the labors of men, fitted by study, rounded and matured by experience, and imbued with that spirit of humanity which knows no distinction between the lowly and the exalted, so far as their claims to assistance are concerned. We regret that into the wheat our good brother has been sowing, tares have crept, and very inferior tares at that. May we not hope that he will be led to see the error of his ways and bring forth fruits meet for repentance?

COMPENSATION FOR CASUAL ATTENDANCE ON RAILROAD INJURIES.

An interesting case on the compensation of physicians for services rendered to an employee of a railroad company, accidentally injured, was recently tried in an Indiana court.

A brakeman on the Terre Haute & Logansport R.R. had his leg crushed by an accident occurring at night, and the conductor of the train asked a surgeon living at Frankfort, the place of the accident, to attend the case. There was no superior officer of the company at Frankfort, but only a resident agent. This agent knew of the employment of the surgeon by the conductor, and although in telegraphic communication with the main office of the company, did not send the officers information.

Upon these facts the railroad company refused to pay the surgeon's bill, on the ground that he had not been employed by the proper officers, and that the action of the conductor was unauthorized. This defence was considered at length by the court and overruled. The verdict for $100 secured by the surgeon was affirmed.

In the course of the opinion the court said: "Suppose the axle of a car to break because of a defect, and a brakeman's leg to be mangled by the derailment consequent upon the breaking of the axle, and that he is in imminent danger of bleeding to death unless surgical aid is summoned at once; and suppose the accident to occur at a point where there is no station, and when no officer superior to the conductor is present, would not the conductor have authority to call a surgeon? Is there not a duty to the mangled man that some one must discharge? And if there be such a duty, who owes it, the employer or a stranger? Humanity and justice unite in affirming that some one owes him this duty, since to assert the contrary is to affirm that upon no one rests the duty of calling aid that may save life."

News of the Week.

Presbyterian Hospital, N. Y.—Dr. F. A. Burrall has resigned his place of attending physician to the Presbyterian Hospital.

Vaccinating for Anthrax in India.—Acting on the suggestion of Mr. J. Mills, the inspector of cattle disease for Madras, the Government of India some time ago decided to test the efficacy of M. Pasteur's "vaccine" for the protection of animals against anthrax, and a set of official papers stating the results has just been published. Ponies, donkeys, cows, bullocks, buffaloes, sheep, and guinea-pigs have all been protected by vaccination from the consequences of inoculation with virus which proved fatal to unvaccinated animals.

Medical Jubilees in Vienna and Prague.—Professor Hyrtl's jubilee has just been celebrated at Vienna, and several graceful addresses were received, including one from the "Verein Deutscher Aerzte zu Prag." Besides the celebrated work on Anatomy, Hyrtl has occupied himself of late years with philological work. In 1879, he published (at Vienna) "Das Arabische und Hebräische in der Medicin," and, in 1880, the "Onomatologia Anatomica." Professor Hyrtl has, says the *British Medical Journal*, taught anatomy to two generations of medical men, and certainly deserves to enjoy his *otium cum dignitate* so well earned. Professor von Jaksch, of Prague, also lately attained his jubilee year as a doctor of medicine, and the occasion was seized for showing the great respect which is felt toward this teacher of clinical medicine, especially as regards methods of physical investigation. Von Jaksch is esteemed for his works on syphilis of the central nervous system, ulcer of the stomach, and the spontaneous cure of heart disease, besides his later labors on acetonæmia, and, finally, the symptomatology of hysterical nervous diseases.

An International Sanitary Conference at Rome.—Proposals have long been on foot for holding another International Sanitary Conference, to discuss the question of quarantine, and, if possible, to draw up international regulations; for various reasons, however, the proposal has never taken practical shape until recently. The Conference which will probably soon assemble had its origin in a proposal made by the Italian to the English Government in August, 1883, to hold an International Conference at Rome; the primary object was to concert a line of action with regard to the regulation of quarantine against cholera. After many delays and much discussion of the grounds upon which Great Britain would be willing to take part, it has been finally arranged, says the *British Medical Journal*, that the Conference shall meet at Rome this or next month, unless any fresh European complications arise in the interval.

Another Convert to Koch.—Dr. Antonio Ceci, of Genoa, as the result of his experiments with pure cultures of the cholera bacillus, comes to the conclusion that it is the specific cause of cholera. He has produced choleraic symptoms by injections of pure cultures of the bacillus into the intestines of rabbits and guinea-pigs.

Increase of Cancer in Baltimore.—Dr. A. R. Carter, Secretary of the Health Department, has compiled a table of the deaths from cancer in Baltimore, for each year, from 1830 to 1885. The list shows a steady increase in the number of deaths from this dread disease. Commencing with seven fatal cases in 1830, the record shows a gradual increase of the figures until, in 1884, the number of deaths reached 182. In 1830 the city contained about 80,000 inhabitants. Therefore, while the population has only grown five times as large, the number of deaths from cancer has increased twenty-six times. Below will be found a statement of the number of deaths from cancer computed by decades: From 1830 to 1840 the cases numbered 81; from 1840 to 1850, 135; from 1850 to 1860, 193; from 1860 to 1870, 389; from 1870 to 1880, 1,051; from 1880 to 1884, inclusive (five years), 848. A striking feature in Dr. Carter's compilation is the remarkable increase during the past ten years, as compared with the forty-five years preceding. From 1830 to 1874, inclusive, the aggregate number of deaths was only 1,116, while for the ten years from 1875 to 1884, inclusive, the mortality foots up 1,581.

Treating the Insane in Tents.—In accordance with recommendations of the Trustees of the Binghamton State Asylum for the Chronic Insane, the State Board of Charities and the State Commissioners of Lunacy have decided to provide tent accommodations for the temporary shelter of two hundred patients for the coming season. The measure was adopted in view of the crowded condition of the asylum, and for the purpose of securing better curative agents in the treatment and care of certain classes of patients. Tents will be erected on the asylum grounds, according to the plan of a well-appointed hospital camp.

Sanitary Precautions.—At a meeting of the State Board of Charities, April 16th, the following resolution was adopted:

Resolved, That the managers and officers of charitable and reformatory institutions throughout the State be, and they are hereby earnestly requested to make a critical examination of the institutions under their charge, for the purpose of determining whether they are in all respects—but especially as to sewerage, plumbing, water supply, and the proper disposal of filth—in the highest possible sanitary condition, to the end that these establishments may, in the emergency contemplated, prove healthful restorative agencies instead of centres for the propagation of disease, as is otherwise possible.

Reports of Societies.

AMERICAN SURGICAL ASSOCIATION.

THE annual session was held in the Library of the Army Medical Museum at Washington, April 21, 22, 23 and 24, 1885.

FIRST DAY—TUESDAY, APRIL 21ST—MORNING SESSION.

The Association was called to order by the President, WILLIAM T. BRIGGS, M.D., of Nashville.

PRESIDENT'S ADDRESS.

After speaking of his appreciation of the honor conferred by his election to the Presidency of the Association, he proceeded to give an extended eulogy of the late Professor S. D. Gross, referring particularly to the fact that the Association owed its existence and, to a great extent, its present vigor to his activity, and this he considered should be an incentive to his successors to increase its efficiency. However, a few suggestions might with propriety be made, the adoption of which would tend to the good of the society. The first that he referred to was the limited number of members. Every reputable surgeon should be included in the ranks of the American Surgical Association, thus each year adding to its strength and vigor. While the election of new members should not be conducted indiscriminately, yet the Society should not have the reputation of a close corporation, for the co-operation of all was required to make it a success. If, in order to carry out this idea, an alteration of the Constitution be necessary, it should be made.

He also suggested that the annual session be held in August or September instead of April or March, as is at present done. This would come at a time when the Fellows would be better able to attend the meetings.

It was also suggested that a certain number of foreign surgeons should be enrolled in the list of honorary members.

The meeting then went into executive session.

On motion the suggestions of the President were referred to the Council.

Volunteer papers being called for,

DR. DAVID PRINCE, of Jacksonville, Ill., presented a paper describing

A DEVICE FOR THE PURIFICATION OF THE AIR OF ROOMS USED FOR OPERATIONS.

The following is a description of such a device :

1. *Basement.*—On the right hand is an entrance ventilator, twenty inches in diameter, in which a steam jet is made to play in order to infiltrate the entering air with very fine globules of water.

2. The air thus moistened passes under a curtain or diaphragm reaching within fifteen inches of the floor. Under this curtain lies an iron pipe with numerous small holes drilled in the upper side, furnishing an interrupted spray under the curtain, and making it necessary for all the moving air to pass through this artificial shower near to the floor and into the next room, warmed by a stove.

3. The air, thus warmed, passes through a filter, composed of shelves of thin muslin, through which water is dripping. The warmed air first passes over the top of a vertical screen to avoid the entrance of cold air, then under another vertical screen, and then back and forth between horizontal screens fifteen inches apart, dripping with water, and finally through the spray which supplies this water.

Thus there are three filtrations of the air, one by steam and two by water.

4. The air, thus filtered three times, emerges through an opening in the floor and goes to the top of the operating room above.

5. *Operating Room.*—The exit ventilation is on the opposite, or right hand side of the room. This is effected by a movable shaft or box, made by tacking muslin upon a frame, so that it can be set up against a window, with the upper sash pulled down to the necessary degree. The shaft can be shifted from one window to another to be free from the pressure of the wind, or on the opposite side, or from the wind. The arrangement thus far is to get an atmosphere more pure than that outside, and through the frequent change of air in the operating room, to get rid, to the greatest possible degree, of the contamination of the air (during the progress of an operation) by the emanations from surgeons, assistants, spectators, and the patient himself. This change is secured by the entrance of filtered air from the basement and the exit, from the floor of the operating room, of the air which has been the longest in the room, having descended gradually from the ceiling where the air is hottest, after having entered from the warming chamber below.

6. The floor of the operating room is made of yellow pine, and filled with paraffin to as great a depth as heated smoothing-irons can drive it. By this means all cracks are filled so as to be non-absorbing. Under this lies a layer of tarred paper upon a common floor upon the joists. Between the joists lies a layer of tarred paper upon the ceiling, the under side of which ceiling is painted, and lined with muslin while the paint is fresh. The muslin is again painted on the under side. The floor thus has seven layers, including the joists.

7. The operating room is free from closets where anything unclean can be hidden, and all wood work is either paraffined or painted.

8. There is no opening into any other room ; about six feet of space intervening between the door of entrance and the nearest wall of the main building.

9. Before the use of the room for an operation involving the opening of a joint or the peritoneal cavity, it is intended that the rooms above and below shall be fumigated by sulphur burning in the basement. An iron pan for this purpose rests over a Bunsen burner for the combustion of sulphur. This is to be done for the destruction of any floating material of an organic character which may have gained entrance while the room may have been out of use.

It is found by trial that when the different sprays of water are going, one can remain very comfortably in the room above while sulphur is burning in the room below ; the fumes, being first absorbed by the steam and having then to pass through the two different showers of water, become thoroughly precipitated.

10. This building is the execution of a theory of combining the best known expedients for securing the best possible atmosphere for surgical operations, by excluding noxious agents and by destroying or expelling those which may have stolen in, or which may be introduced by the patients, or by the surgeon and his assistants and guests. It is supposed that enough air will enter and escape to change the whole volume of the air once in fifteen minutes. The exit draught coming from the floor will carry away most of the floating material.

11. The employment of a spray or douche of carbolic acid of the strength of 4 to 100, or of mercuric bichloride of 1 to 10,000, or other antiseptics, locally applied, though less necessary than in an ordinary room, may yet be resorted to in order not to omit any useful precaution.

12. The employment of solutions of carbolic acid, mercuric bichloride or permanganate of potash with the nail-brush for cleaning the hands should be supplemental to the fixed provisions against septic and pathogenic particulate infection.

13. The bathing of the instruments in carbolized water, while this proceeding is incapable of disinfecting or destroying any germs which may adhere to them, may yet be useful in an antiseptic sense, *i.e.*, by destroying microbes in a developed state or freeing them from the supposed secretion by which they may be surrounded, and which may serve as their weapon of attack by which they digest or destroy the surfaces with which they come directly in contact.

14. A useful precaution on the part of the operator may be a bath and a change of clothing, the hair and head being dampened so that dust will not escape from them; and yet another precaution may be the wearing of gowns which will oblige all dust escaping from the clothing of the operator and his assistants to fall to the floor, whence it may escape with the draught which carries out the lowest stratum of the air.

Adjourned.

Afternoon Session.

Dr. John B. Roberts, of Philadelphia, read an address on

the field and limitation of the operative surgery of the human brain,

in which the following views were advanced:

1. The complexus of symptoms called "compression of the brain," is not due so much to displacing pressure exerted on the brain substance as it is to some form or degree of intracranial inflammation.

2. The conversion of a closed (simple) fracture of the cranium into an open (compound) fracture by incision of the scalp is, with the improved methods of treating wounds, attended with very little increased risk to life.

3. The removal of portions of the cranium by the trephine or other cutting instruments is, if properly done, attended with but little more risk to life than amputation of a finger through the metacarpal bone.

4. In the majority of cranial fractures the inner table is more extensively shattered and splintered than the outer table.

5. Perforation of the cranium is to be adopted as an exploratory measure almost as often as it is demanded for therapeutic reasons.

6. Drainage is more essential in wounds of the brain than in wounds of other structure.

7. Many regions of the cerebral hemispheres of man may be incised and excised with comparative impunity.

8. Accidental or operative injuries to the cerebral membranes, meningeal arteries, or venous sinuses should be treated as are similar lesions of similar structures in other localities.

9. The results of the study of cerebral localization are more necessary to the conscientious surgeon than to the neurologist.

An elaborate table of the proper points for trephining in various cerebral lesions was then given.

These principles of the operative surgery of the brain were then applied to the treatment of

A. *Cranial fractures.*—Closed (simple) fissured fractures: 1, No evident depression, no brain symptoms—no operation; 2, no evident depression, with brain symptoms—incise scalp and trephine; 3, with evident depression, no brain symptoms—incise scalp and possibly trephine;[1] 4, with evident depression, with brain symptoms—incise scalp and trephine. Closed (simple) comminuted fractures: 5, No evident depression, no brain symptoms—incise scalp and probably trephine;[2] 6, no evident depression, with brain symptoms—incise scalp and trephine; 7, with evident depression, no brain symptoms—incise scalp and trephine; 8, with evident depression, with brain symptoms—incise scalp and trephine. Open (compound) fissured fractures: 9, No evident depression, no brain symptoms—no operation, but treat wound; 10, no evident depression, with brain symptoms—trephine; 11, with evident depression, no brain symptoms—possibly trephine;[1] 12, with evident depression, with brain symptoms—trephine. Open (compound) comminuted fractures: 13, no evident depression, no brain symptoms—probably trephine;[2] 14, no evident depression, with brain symptoms—trephine; 15, with evident depression, no brain symptoms—trephine; 16, with evident depression, with brain symptoms—trephine. Punctured and gunshot wounds: 17, in all cases and under all circumstances trephine.

B. *Intracranial hemorrhage.*—Trephine for the removal of clot and arrest of bleeding when the probable seat of hemorrhage is ascertainable, and the clot is believed to be a localized one.

C. *Intracranial Suppuration.*—Trephine and make if necessary exploratory punctures in all cases of abscess.

D. *Epilepsy following cranial injury.*—Remove portion of cranium in selected cases.

E. *Insanity following cranial injury.*—Remove portion of cranium in selected cases.

F. *Cerebral tumor.*—If can localize it, and if it is probably superficial, remove bone; and excise growth if it is found.

Dr. Hunter McGuire thought that the adoption of the rules laid down by Dr. Roberts would carry us back at least one hundred years. Such doctrine he considered most injurious, especially in its influence on the younger members of the profession. No positive rules can be laid down for the treatment of fractures of the skull, every case must be treated on its own merits.

He took exception to the first proposition advanced by Dr. Roberts, claiming that in those cases where the symptoms followed immediately the reception of an injury to the skull they were due to compression from bone. He did not consider the operation of trephining such a simple one. Drainage is an important element in the successful result and he had removed a portion of the scalp in order to the more surely obtain thorough drainage.

He presented the button of bone removed from a case of epilepsy in which, while there was no depression of the external plate, there was marked depression of the internal plate. During the operation a large portion of the cerebro-spinal fluid escaped, but the patient recovered. He also referred to the case of an insane patient who for nine years had not spoken a word. In this case there was a depressed fracture from a blow with a boat-hook. Within a few hours after the operation the man became rational and was able to talk, but had no recollection of the events which had transpired since the receipt of the injury.

Dr. Moses Gunn, of Chicago, stated that three years ago he had presented a paper on the same subject, at that time taking the ground that in fracture of the skull with depression, the bone should be elevated even if the fracture were a simple one. This he considered justifiable on account of the improved methods of treating open wounds. Dr. Gunn agreed with Dr. McGuire in his statement that there were some cases of compression of the brain which could not be explained by the existence of inflammation. The danger in fractures of the skull is not from the mechanical compression produced, but from the secondary irritation and inflammation which is excited.

Dr. Charles B. Nancrede, of Philadelphia, agreed with Dr. Roberts in many points, while in others he could not agree with him. It might have been stated with truth that secondary compression of the brain was due to intracranial inflammation. The conversion of a simple fracture of the skull into a compound one he considered did increase the risks of the patient. Besides this, in the operation of trephining the brain is exposed to certain accidents and complications of a serious nature. Drainage is of much importance.

Speaking of injuries of the sinuses, he said that where he suspected such an injury he always treated the case as though that were really present, and detailed a case of hemorrhage from the superior longitudinal sinus in which the bleeding was controlled by a compress treated with iodoform. The patient recovered.

In reference to the location of the lesion from the symptoms, he thought that the motor centres were pretty

[1] In classes 3 and 11 he would be inclined to trephine if the depression were marked, or the fissures sufficiently multiple to approach the character of a comminuted fracture.

[2] In classes 5 and 13 he would trephine, unless the comminution were found to be inconsiderable.

well established, but that much care must be exercised where the irritation affects the sensory nerves, and cited one case in which a mistake might readily have been made. He divides fractures of the skull into three classes, one which will die no matter what is done, another class in which the patient will recover if the secondary results are prevented, and a third class between these two which requires careful treatment.

He thought that the puffy tumor did not indicate absolutely the presence of pus, but it did indicate osteomyelitis which was frequently associated with inflammation. In those cases where that had been a pure cerebral abscess the temperature was either normal or sub-normal.

In regard to foreign bodies, patients sometimes recover with such bodies within the cranium, but this is less likely to occur and less apt to be permanent than where the foreign body has been removed.

Dr. Washington F. Peck, of Iowa, agreed with many of the opinions expressed by the author of the paper. He thought that the direct pressure of bone was capable of inducing cerebral symptoms. These symptoms more frequently are due to the products of inflammation. He referred to a patient seen by him in which a man had been struck in the temporo-parietal region and immediately exhibited the symptoms of compression. He remained in this condition for twenty-four hours. Trephining was done and the patient gradually regained consciousness. A few days later he had a convulsion, and an incision into the brain evacuated about an ounce of pus. The patient recovered.

In a second case, that of a boy shot a little to the left of the middle of the frontal bone, there was immediate symptoms of compression. The trephine was employed, and a large clot of blood escaped. To encourage free drainage, a poultice was applied. The boy is now perfectly well, although the ball was not removed.

In a third case, a child received a depressed fracture from a blow with a piece of coal. There were no symptoms of compression and he performed no operation, and the child is doing well.

Dr. Theodore F. Prewit, of St. Louis, thought that the propositions laid down should not go out without a thorough discussion. He thought that the first proposition had already been sufficiently discussed. The sign of compression may, however, be due, not only to the presence of depressed bone, but to the formation of a clot. Although the second proposition might be true, still that would not render it advisable to tap in every case. The results of a fracture of the skull are not due so much to the fracture of the bone as to the injury of the brain-structure and meninges. The bone will repair itself without trouble, but the danger is in proportion to the amount of brain injury.

Although with antiseptic precautions we had greater control of inflammation, yet all authorities were not agreed as to the value of antisepsis, some refusing to use it at all. Compound fractures, wherever they may occur, are always more serious than simple fractures. The brain will bear a certain amount of compression from bone without apparent damage, and it is frequently noted that depressed fractures in children may disappear without treatment. Trouble follows in those cases where the brain and membranes are irritated.

In regard to class B, if he thought hemorrhage were going on it would be advisable to trephine, but if the symptoms were not urgent, it would be better to wait, for after a time the blood would be absorbed. In reference to proposition 5, he thought that it allowed a wide margin and that the doctor would not be willing to permit such a wide latitude in his own case.

Dr. Charles T. Parkes could not agree in the first proposition so far as to say that symptoms of compression were entirely due to inflammation. These symptoms often occur immediately and disappear as soon as the cause of depression is removed. Even if the second proposition were admitted to be true, he did not think it right to give the patient even a slight increase of risk without it was necessary. Although drainage is important, yet it is difficult to carry out. He referred to a case under his care in which there had been two or three fractures of the skull. There was a depressed one at the vault which was trephined. The membranes were not injured. A drainage-tube was introduced. There were no symptoms of compression during the next few days. On the fourth day there was the escape of a large amount of cerebro-spinal fluid, which soaked the dressings and pillow. He referred to the rarity of this accident and explained it on the supposition that there was a laceration into the ventricle. This has been found to be the case in an instance recently reported by Mr. Lucas, in "Guy's Hospital Reports."

In regard to injury of the vessels of the brain, in one case which I saw there was free bleeding from an opening in the longitudinal sinus, which, after trying other expedients, I checked by introducing three catgut sutures. The patient recovered.

In regard to the localization of the injury, I have a case bearing on that point. A man was struck with the barrel of a pistol in the upper and outer portion of the parietal bone. There was a large loss of brain-substance. I removed a piece of bone with the trephine, and during the operation still more tissue escaped. On introducing the finger, I found that it passed to the tentorium of the cerebellum, and there I found the sight of the pistol which had been broken off. According to the view expressed by Dr. Roberts, this man should have had almost entire loss of sensation. The Doctor also spoke of the importance of drainage, and cited an illustrative case.

Dr. J. Collins Warren, of Boston, thought that drainage in these cases was difficult on account of the intercranial pressure forcing the tissues up and blocking the opening in the bone. Here there is pressure of the brain on a sharp edge of bone, and this may cause irritation.

The speaker then referred to the difficulties of diagnosis. In one case a child with a depressed fracture of the upper anterior cranial vault presented no brain symptoms, although there was some fever for a week. Then the child became completely deaf. At the autopsy there was found slight depression and pus was found in the fourth ventricle.

In a second case the patient was unconscious and delirious for four weeks before he died. No evidence of brain-lesion could be found at the autopsy, but a considerable quantity of blood-clot was found in the abdominal cavity. He then referred to the fact that cellulitis and periostitis of the tissues at the back of the neck might be accompanied with brain symptoms, and related two cases in which they were seen. Concussion of the brain must also be considered in the diagnosis.

In referring to the subject of the localization of brain-lesions he described a case in which it was thought that there had been hemorrhage at the vault of the cranium, involving the centre of motion for the legs, and that this had gradually gravitated to lower portions of the surface, for there was first paralysis of the leg, then of the arm, and then of the face, and the paralysis recovered in this order.

Dr. L. M. Tiffany agreed with the majority of the previous speakers in reference to the non-advisability of converting a simple into a compound fracture, and in regard to exploratory trephining.

He considered it important to make a distinction between fractures occurring in childhood and the same fractures occurring in adult life. A distinction is also to be made between such injuries in the colored and in the white race. In the former shock is infinitely less and inflammation follows quite a different course from what it does in the white.

In those cases in which there was no depression and no symptoms he could not understand where the trephine should be applied. Frequently the injury is on the opposite side of the brain.

Dr. S. W. Gross, of Philadelphia, thought that there might be such a thing as fracture of the skull without evident depression and without brain symptoms. These were frequently met with in the army. These are cases of linear fracture. In such a case the dura mater may be separated from the bone and the effusion of blood may give rise to symptoms of compression, which, however, come on more gradually than when there is a laceration of the anterior branch of the middle meningeal artery.

He considered a compound fracture of the skull more serious than a simple fracture. It is more difficult to carry out strict antiseptic precautions in such cases. Drainage is more essential in wounds of the skull than in other injuries. The drainage should be as thorough as possible, and reference was made to a case of Dr. Noyes, in which a counter-opening was made at the vault of the skull, a tube passed through and the patient recovered.

In regard to the classes B, C, D, and E, there could be no question. In regard to cerebral tumors, more experience is required. The Doctor then referred to gun-shot injuries of the skull. In such cases the opening should be enlarged and the finger or a suitable probe introduced to determine the direction of the wound and to remove the foreign bodies that may be present.

He deemed it of great importance to apply to the brain the same rules as are applicable to other soft tissues of the body.

He referred to an extraordinary case described recently in the New York Medical Record, in which a case of gun-shot injury was seen by Fleura. It was found that the bullet had passed completely through the brain and impinged on the opposite side. A trephine was applied at this spot and the missile found half an inch below the surface.

Dr. Edward H. Moore, of Rochester, arose, not so much to discuss the paper directly, as to make some remarks to which he was incited by the words of Dr. Gross. He advocated more radical measures in the treatment of gun-shot injuries of the brain than is commonly done. When a ball traverses the brain, it is not usually found at the point where it strikes, but is reflected a little below this point. In his last case he had made a counter-opening and found the missile. He then attempted to carry a drainage-tube through but was not successful. He thought that it would have been better if he had persisted in his effort.

The further discussion was adjourned until 10 A.M. Wednesday. Adjourned.

Second Day—Wednesday, April 22d—Morning Session.

The Association was called to order by the President, after which

THE DISCUSSION OF DR. ROBERTS' PAPER

was resumed.

Dr. David Prince, of Jacksonville, Ill., thought that the use of antiseptics placed trephining among the safest of operations. Where such precautions cannot be taken the result is very different. He described a case of compound comminuted fracture in which he trephined and made the proper antiseptic applications, but the patient refused to allow them to remain and died of septic meningitis. The use of these precautions enables us to make exploratory operations without the fear of doing harm which was formerly experienced.

The paper had not insisted upon what he considered an essential in the treatment of these cases, and that was absolute rest. He thought that the parallel between compound fractures of the skull and compound fractures of the thigh was correct with one difference, and that was that in the skull, the circulation being more active, the cure is more rapid.

Dr. John H. Brinton, of Philadelphia, said that the first thing the surgeon did on being called to a patient suffering with the symptoms of compression was to examine for depressed bone, which produces the symptoms which we desire to relieve by elevation. He described a case of fracture in a boy seventeen years of age, in whom the fracture extended from the external to the internal angular process, the upper portion of the frontal bone overlapping the lower portion. The bone was at once sprung into position by the use of the elevator and almost immediately the patient recovered consciousness and talked rationally.

He believes in the early use of the trephine, but he did not believe that trephining was a trivial operation.

The treatment of most cases of fracture of the skull is clear. Where we have a compound fracture with or without symptoms, and with depression, the treatment is plain. The only cases in which there is doubt is where there is a simple depressed fracture without any, or with only slight symptoms. If we do not operate the man is exposed to many dangers. The treatment can be summed up in few words. The Doctor then read from Gross' "Surgery" several passages advocating operative measures in these cases.

Dr. T. McGraw, of Detroit, referred to a statement made yesterday that the brain would accommodate itself to pressure. This he did not believe and described a case in support of this opinion. A painter fell from a scaffold, producing a cup-like fracture. No operation was performed and he returned to his work with no apparent symptoms of cerebral irritation. Dizziness began to appear, and, a year after the injury, became so marked that he could not pursue his occupation. He then trephined the skull, removing the depressed portion. The internal surface of the button was perfectly smooth, and the dura mater beneath it was healthy. In that case the brain did not become accustomed to the pressure.

Dr. P. S. Conner, of Cincinnati, thought that by taking away the depressed fragments of bone the patient was given a better chance of avoiding the sequela of these injuries. In the case of children, as already pointed out, we could temporize.

He had been surprised at the confidence expressed in the treatment suggested for gun-shot wounds. It is hard to tell where a bullet goes to after it enters the brain, and, if some authorities are to be believed, the presence of a bullet in the brain does no harm. He did not consider it the part of wisdom to scoop out the injured brain substance, and carry drainage-tubes through. If there is a tract through which thorough drainage can be readily made, very well. In such cases as that described by Dr. McGraw, he thought that other conditions, such as blood-clot would usually be found.

Dr. B. A. Watson, of New Jersey, described a case showing that even in the adult, as well as in children, the brain would become accustomed to a certain amount of compression.

In response to the request of the Association, Dr. Briggs took the floor and gave his views on the subject. He said that this was one of the most vexed subjects in surgery. The excellency of the paper was shown by the amount of discussion which it had evoked. There are two classes of injuries which are very distinct. One is a diffused injury, where the trouble is not located in the cranial walls, and where trephining would be of no service. There is a second class in which the injury is localized to the skull. In these cases it is the bone that is doing the damage, and here the use of the trephine is important. In those cases where the immediate symptoms of compression are attributed to depression, I think that trephining is of no use, for the symptoms are due to some disturbance of the circulation, or of the nervous circulation of the brain, or to some other condition which will not be reached by the trephine.

Where there is hemorrhage the operation is indicated, but usually the patient dies. Where compression is due to formation of pus it is to be evacuated on the same principle that we open an abscess in other portions of the body.

In his opinion the principal and only use of the trephine is to remove points of irritation produced by spicules of bone. We resort to the trephine at the earliest possible moment for the prevention of those conditions which cannot be cured if allowed to progress beyond a certain stage. The operation should be limited to that and to that alone.

Dr. Roberts, in closing the discussion, stated that he would not attempt to reply to all the points which had been brought forward. Many of the Fellows had misunderstood the term compression. A depressed fracture of small extent cannot compress the brain, for the brain is so soft and has a communication with the spinal column, so that the pressure is diffused, and it is only by a depression of a large portion of the cranium that compression can be produced. He distinguished between compression and pressure.

In most of the cases cited the symptoms immediately following the injury are to be attributed to laceration, contusion, or the obscure condition called concussion of the brain. The doctor held that inflammation of the brain might develop very rapidly and illustrated it by a reference to injuries of the conjunctiva which in a short time will produce evidence of irritation. In regard to his comparison of the risks of trephining with the risks of amputation through a metacarpal bone he said that statistics had shown that the risks of trephining were three per cent., while the risks in amputation of the metacarpal bones was 4.5 per cent. In regard to the case referred to by Dr. Parkes, he said that it had no bearing on the localization of brain-lesions, for in that case the destruction of tissue was far below the points which he had indicated.

A careful reading of his propositions would show that he did not advocate trephining as had been represented, in all cases.

In two classes it is contra-indicated, in another set it should possibly be done, in another probably, and in another it should always be done.

He thought that in five years the same opposition would not be made to these views as had been made to-day.

The next paper was entitled

NEPHRECTOMY, ITS INDICATIONS AND CONTRA-INDICATIONS,

by Dr. S. W. Gross, of Philadelphia, who presented a number of statistics showing the result of the operation under different circumstances. From these facts the following conclusions were drawn:

1. That primary extirpation of the kidney is indicated, first, in sarcoma of adult subjects; secondly, in the early stage of tubercular disease; thirdly, in rupture of the kidney or of the ureter; and, fourthly, in benign tumors.

2. That nephrectomy should not be resorted to until after the failure of other measures; first, in urinary fistulæ of the kidney or of the ureter; secondly, in protrusion of the kidney through a wound in the loin; thirdly, in recent wounds of the kidney or of the ureter made in the performance of ovariotomy, hysterectomy, or other operations; fourthly, in suppurative lesions; fifthly, in hydronephrosis and cysts; and lastly, in floating kidney.

3. That the operation is absolutely contra-indicated, first, in calculus of an otherwise healthy kidney; secondly, in sarcoma of children; thirdly, in carcinoma at any age, unless the disease can be diagnosticated and removed at an early stage; and, fourthly, in the advanced stage of tubercular disease.

Then followed a paper on

NEPHROLITHOTOMY,

by Dr. L. McLane Tiffany, of Baltimore. The Doctor described the operation as performed in a young man twenty-six years of age. The stone was exceedingly large and it was found necessary to break it up with a spoon and remove by means of a syringe. The débris collected after the operation weighed five hundred and fifty-six grains and was composed chiefly of phosphate of lime. A drainage-tube was introduced and the wound dressed with oakum and iodoform. The patient recovered without trouble and left the hospital twenty-five days after the operation. The wound in the skin healed perfectly. One fact noted during the treatment was that water injected into the wound would escape into the bladder.

In reply to a question, Dr. Tiffany stated that he thought the incision through the cortex of the kidney better than an opening of the pelvis. He would advocate opening that portion of the kidney which was exposed in the operation, displacing the organ as little as possible.

Dr. J. Collins Warren, of Boston, read a paper on

THE HEALING OF ARTERIES AFTER LIGATION.

After an artery is ligated it is invested with a protective layer of new tissue, formed from the periadventitial tissue, which, if well developed, gives great security against hemorrhage until the permanent cicatrix has grown sufficiently strong. This may be likened to the provisional callus of bone. There is also an internal growth of callus formed from several sources, namely, the intima to a slight extent, the media, more largely, and also from cells finding their way from the periadventitia, at a late stage, through the retracted ends of the vessel. From the muscular layer cells project into the thrombus at an early stage. These develop into spindle-cells closely resembling those forming the muscular layer. The thrombus is merely a passive structure, taking no part in the growth, but is protective, and affords an excellent medium in which the new tissue may germinate. When the provisional part of the internal callus has disappeared, we find remaining a cicatrix closely resembling the three coats of the artery, and affording, by virtue of its peculiar structure, an equally effective resistance to the pressure of the blood-column. The ligament which unites the two ends of the vessel represents in part the residue of the external callus, but also a portion of the walls of the vessel which have been absorbed during the inflammatory process. A vessel successfully ligatured in its continuity cannot, therefore, be said to have been "ulcerated" into two separate portions, but must be conceived of as a hollow tube which has solidified into a solid columnar mass of tissue, a considerable portion of which subsequently shrinks into a cord. The closure of the ductus arteriosus was cited as illustrating a muscular cell-growth.

The formation of the muscular cicatrix was especially dwelt upon as affording protection from aneurismal dilatation.

The remarks were illustrated by specimens from the horse at two weeks, one, two, and four months, and also from the human subject.

Dr. P. S. Conner, of Cincinnati, read a paper on

THE ETIOLOGY OF TETANUS.

Cases classed under this general head may be divided into two classes, one in which the spasms first affect the injured part, the other in which the spasms are primarily located in the muscles supplied by the nerves which have their origin in the medulla oblongata. It has not been positively determined in what way the affection is brought about, whether by the nerves, the blood-current, by extension of inflammation, by reflected irritation, by septic changes, or by the presence and development of micro-organisms.

The speaker then took up each of these theories and reviewed the evidence in favor of and against them. Special attention was paid to the septic theory, the speaker considering that the balance of evidence was in favor of this being the origin of tetanus.

The Association then adjourned and the afternoon was devoted to a visit to the Johns Hopkins University, at Baltimore.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 15, 1885.

A. Jacobi, M.D., President, in the Chair.

PRESENTATION OF THE PORTRAIT OF FORDYCE BARKER, M.D., LL.D. (EDIN.).

Dr. Thomas M. Markoe delivered the following address with the presentation of a three-quarter length and handsomely framed oil-painting by Lazarus :

"It is my pleasant duty, on this occasion, on behalf of the generous donor, to present to you, Mr. President and Gentlemen, Fellows of the Academy, this beautiful portrait and admirable likeness of our former president, Dr. Fordyce Barker. My office is a very modest one, and is soon discharged. I am here merely as a representative, an ambassador, if you please, charged with a valuable gift which I am here and now to present to the dignified body over which you, sir, so worthily preside.

"I must acknowledge some little hesitation in appearing before you to-night, lest it might be considered somewhat presumptuous in me, stranger, as I am, to your hall and to your councils; unknown by voice or face to so many of my auditors, to appear at all on your platform. I have accepted the duty as a friend of all parties, and in undertaking it I felt sure I could entirely rely on your courtesy and kindness, and that, while some more familiar voice and some better known figure might have been more acceptable, yet no one could, better than I, appreciate and interpret to you the generous liberality which has inspired the gift we are here to-night to accept; and I am sure none could feel a more heartfelt gratification at the compliment which your acceptance of this portrait will confer on a dear and much-valued friend.

"The gift itself is a costly and valuable one. To us, however, far above its cost, lies its greater value in what it suggests of warm and kindly appreciation, on the part of the great world outside of our profession, of the aims, the motives, and the achievements of the medical science of to-day. This offering means no chance suggestion, or accidental impulse to do a praiseworthy deed for the sake of merely giving pleasure to friends, or to produce a dramatic effect which might afford society a topic of pleasant conversation. It means much more. It means a well-considered and intelligent conviction of the worthiness, and reliability, and ultimate success of our efforts for the relief of human suffering, and a most gratifying assurance that those efforts are, at least in some degree, appreciated by an interested and generous public. In this point of view, it seems to me that this beautiful and appropriate tribute may fairly be accepted as marking a favorable public sentiment, which is as flattering to our professional pride as this testimonial of it is gratifying to our personal feelings. In pleasing ourselves, however, with this general view of the kindly relations which this occasion emphasizes between the profession and the public, we must not for a moment overlook the testimony it bears to the personal regards of the distinguished giver. The same generous hand which has now adorned our gallery with this beautiful portrait, has in years not long gone by enriched our guild with the graceful "loving cup," the token of peace and harmony, in which we drink to concord and enduring friendship among ourselves. I am sure I voice a unanimous sentiment when I offer our heartiest thanks to Mrs. J. J. Astor for this valuable and appropriate gift to the Academy.

"This counterfeit presentment of our eminent associate is now to grace the walls of this assembly room, taking its place among a group of faces which the Academy cherishes, as of those whom it delights to honor. There smile upon us from these walls the faces of many, alas how many! who have gone from us, leaving their noble record as an inheritance, by which we are enriched indeed. There are some who still remain, to lend us their mature counsel, and guide us in our sometimes difficult way. One stands conspicuous, as the only rival of our recent president in the length of time he has served us in the highest office within our gift, whose blameless life and devoted loyalty to the highest standards of professional honor, mark him as the Nestor of our profession. May he be long spared to adorn it.

"Our thoughts to-night, however, are on the present rather than on the past, and on him whom we are about to honor, rather than on those whose loved memories reflect such high honor upon us. This is not the occasion, nor has the time yet arrived, when our esteemed friend's eulogy may be fitly spoken. '*Finis coronat opus.*' May it be long before that coronation day arrives. But this is the place, and this an appropriate time, when we may recall the many happy relations he has borne to us as our presiding officer, through what has certainly been the most anxious and critical period in the history of the Academy. Not hesitating to avow himself a partisan, and even a leading champion of the cause he believed to be right, yet his high sense of honor, a clear appreciation of what was just and fair toward each of the bitter factions into which, unfortunately, our camp was divided, gave him so entirely the confidence of both, that he was able, with a courageous but impartial hand, to mollify the rancor and moderate the excesses of both sides in the arena of debate, and, in my judgment, largely to contribute to the peaceful and final settlement of the burning questions in dispute on the only basis upon which such questions can ever be settled, namely, a willingness to concede sincerity of conviction to those who are opposed to us, and a manly and honest consent to a friendly disagreement, where cordial agreement has become impossible. I feel sure that my audience will concede this much to a man whose personal relations to the struggle were never, for a moment, left in doubt, and whose convictions were so clear as to make him a tower of strength to the side he so warmly espoused, and to which victory was finally awarded. That this estimate of his course and character was substantially that of the whole Academy, subsequent events clearly demonstrated.

"When, in an evil hour, influenced by motives which we do not care to analyze, and urged with a well planned and deliberate purpose, which seemed strongly to savor of bitter personal ill-will, charges were formally brought against our president by a number of fellows who had collected their evidence with infinite pains, both here and abroad, and who, it must be acknowledged, presented their damaging accusations with admirable skill and telling minuteness of detail, it did seem to all of us that a crisis in the affairs of the Academy, and one of a most serious nature, had really come upon us. If the accused, occupying the conspicuous position he held, had really been guilty of deliberate falsification, and had profited for so many years by the results of his gross deception, the question might well be asked, Who, then, can be trusted? With what calm, unimpassioned completeness he met these baseless fabrications, and with what unanswerable documentary evidence he utterly refuted them, must be fresh in the memory of all. That he should have been acquitted—triumphantly acquitted—by a unanimous vote, was due to the plain, convincing, and perfect proof which his own simple narrative afforded, and to the calm good sense of the Academy, which immediately perceived its justice. But the universal and heartfelt applause which followed the announcement of the verdict, the outspoken pleasure at the vindication of a friend, and the warm congratulations expressed on all sides and by all parties, were, and no one could fail to see that they were, testimonials of hearty good-will toward a man, and gratification that one so high in their regard should have emerged so triumphantly from what seemed to them so cruel, so heartless, and so perfectly unnecessary an arraignment. But enough of this. My own feelings have led me, perhaps, too far in dwelling upon these personal considerations, and I forbear.

"The ceremony of the occasion, Mr. President and

Gentlemen, is over. You are now the possessors of this beautiful addition to your already rich collection. It is a worthy admission into a goodly company, and as I look around on these faces, so closely associated with my earliest and best impressions of professional life, I cannot help pleasing myself with the thought that, long years hence, it may be, as our children or grandchildren, curiously scanning the faces of the noble group, ask who was this and who was that, some white-haired relic of this present assembly may say, 'This is the portrait of one of our most eminent and of our best beloved presidents, *Dr. Fordyce Barker*.' "

The chaste, kind, expressive, and yet uncompromising language of the presentation address was listened to with that profound silence which comes only with deep, heartfelt interest in the welfare of a tried friend and brother, and which bursts into spontaneous applause when the spell is broken.

The President accepted, in behalf of the Academy, the beautiful gift as a well-merited homage from the midst of an intelligent and high-minded public interested in the prosperity of the medical profession, and expressed his gratification in the fact that it came from one by whom the material interests of the Academy had heretofore been liberally and kindly advanced. The gift was continued proof that the public take an interest in the medical profession, and when it took an interest in the best of the profession the best interests of the public were very much enhanced.

Dr. Alfred C. Post moved that the thanks of the Academy be presented to the donor for this valuable gift and unusually beautiful work of art. Unanimously carried.

Dr. Heineman moved that the thanks of the Academy be tendered to Professor Markoe for his kind and beautiful presentation address. Unanimously carried.

Dr. James B. Hunter then read a paper (see p. 449) on

ENDOMETRITIS FUNGOSA.

The discussion was opened by Dr. W. Gill Wylie, who could accept the greater part of Dr. Hunter's paper, but especially that which pertained to the pathology of the affection.

With reference to treatment, he had some objections to the recommendations of the author of the paper. He agreed with Dr. Hunter's statement that the use of the curette was seldom followed by hemorrhage of much consequence, and was surprised when he heard him also state that he introduced a light tampon after the operation. If there was no hemorrhage, Dr. Wylie would never use the tampon, because its use under such circumstances was a violation of one of the first rules of surgery, and if there was hemorrhage he preferred to arrest by other methods, as twisting or ligation of the circular artery, if that was injured, or the use of hot or cold water, or styptics, if the hemorrhage came from small vessels. Even if thoroughly aseptic, tampons were objectionable because the external flow of blood being arrested, the fluid might fill the uterus, be forced through the Fallopian tubes into the peritoneal cavity, and there give rise to very serious complications. He would advise the use of tampons in those cases only in which there was the greatest necessity.

He would always dilate the uterine canal to some extent before curetting, and for the purpose of securing perfect drainage. Even when the cervix had been made patulous by the fungous growths, he preferred to dilate somewhat, and by means of a steel dilator, never using tents of any kind.

Concerning the kind of curette to be employed, Dr. Wylie preferred the instrument used by Dr. Sims during the latter years of his life, which was not a sharp curette, and had a universal curve. The dull curette was useless in some forms of fungous degeneration of the endometrium, especially when the growths were a trifle fibrous and tough.

Dr. Paul F. Mundé would like to say, with reference to the quotations concerning the frequency of the occurrence of uterine sarcoma, which Dr. Hunter had made from one of his papers, that doubtless the disease occurred more frequently than was there represented; but it must be borne in mind that since the writing of the paper, seven years ago, the literature of the subject had accumulated very greatly.

With regard to diffuse hyperplasia of the endometrium, however, Dr. Mundé still stood by what he had published on that subject from a clinical standpoint only, as he had no evidence to adduce furnished by the microscope. He believed that different forms of endometritis, with different modes of development, occurred and yet produced the same symptoms and called for the same treatment. Diffuse hyperplasia was one of these forms, that in which diffuse slices, as it were, of hyperplastic tissue could be removed.

There was one class of cases, not mentioned by the author of the paper, namely, that in which the fungous endometritis was a direct sequence of laceration of the cervix; the order of events was clear, and the cases were numerous, and there was nothing more certain in therapeutics when these cases were treated in the inverse order, namely: 1. Scraping out the uterus; 2, restoring the mucous membrane to a healthy condition by local applications of iodine, etc., and 3, uniting the laceration of the cervix.

As regards symptoms of endometritis fungosa, menorrhagia was the universal symptom with only rare exceptions; but Dr. Wylie's mention of its occurrence with amenorrhœa brought to mind one case which he had had in which the patient had irregular menstruation, with menorrhagia at times, and at other times, there was absence of menstruation.

Dr. Mundé regarded the sharp curette as a very dangerous instrument to be used above the internal os, although he had employed it in cases where the dull curette had been insufficient to destroy the diseased mucous membrane. In some cases he thought it was necessary to use the sharp curette, but it was unnecessary to use one with a stiff shank, with which it was possible to scrape through the wall of the uterus.

Whenever the dull curette was used for diagnostic purposes and anything at all was obtained by the scraping, he regarded the cause of the menorrhagia as chronic endometritis, and the therapeutic indication was to treat that condition.

Concerning the danger of curetting and the after-treatment, he disagreed with Dr. Wylie and agreed with Dr. Hunter, as very considerable hemorrhage might follow the operation and require the use of the vaginal tampon. He thought it was unsafe to leave the patient without something to protect her from hemorrhage, and therefore employed the tampon. As a rule, it was unnecessary to dilate before curetting, although dilatation was not specially dangerous.

Having thoroughly cleaned out the uterus with the curette, and then mopped it out, Dr. Mundé takes an applicator wrapped with cotton, soaks the cotton with iodine or persulphate of iron and glycerine, equal parts, passes it up to the fundus and fills the cavity of the uterus thoroughly, then mops out the vagina and introduces a tampon, which is to be removed within forty-eight hours. This local treatment of the endometrium, preferably by the use of iodine, should be continued twice or three times a week, afterward once a week, etc., until three or four perfectly normal menstrual periods have passed, or until the patient is cured temporarily at least.

Dr. C. C. Lee agreed in the main with the author of the paper, both with reference to pathology and treatment. With regard to symptomatology, however, he had not found the disease characterized uniformly by menorrhagia, but by metrorrhagia as well, although in the great minority of cases.

The second point to which Dr. Lee directed attention

was the occurrence of general passive uterine congestion without alteration of the endometrium, without chronic hyperplasia of the uterus, in feeble subjects chiefly, and with which hemorrhage might be a prominent symptom. He always prepared his patients for the operation of curetting, and preferred to perform it with the assistance of ether. He was unhesitatingly on the side of those who discarded the sharp curette, and thought that, except in the most skilful hands, it was an instrument which was likely to do harm; besides, he saw no reason why it should be used. By proper preparation of the patient the liability of the occurrence of secondary hemorrhage was diminished. He had not found it necessary to dilate before using the curette, because the cervical canal had been sufficiently patulous to allow of the use of the curette in any direction.

Before using the blunt curette Dr. Lee washes out the uterus with a weak hot carbolic solution, and also after the curetting has been completed. He then applies to the endometrium the strong tincture of iodine (never iron), to which has been added a small quantity of chromic acid solution (one part of a saturated solution of chromic acid to four parts of a solution containing equal parts of alcohol and strong tincture of iodine), the combination acting much more favorably than either remedy when used alone.

Dr. B. F. Dawson approved of what had been said by Dr. Hunter and supplemented by Dr. Lee with reference to the use of the sharp curette. He had not seen a case in which while curetting he had been obliged to dilate. He had always found the cavity of the uterus and the uterine canal large enough to allow all the manipulation necessary to thoroughly remove all the fungoid growths. He was strongly opposed to what might be called the ferocity of surgeons, and agreed with Dr. Lee that gynecologists should be very careful how they recommend to the profession the use of so dangerous an instrument as the sharp curette.

Dr. Hunter, in closing the discussion, said that by a light tampon he meant simply the introduction of two or three small wads of cotton, to effect drainage and not to prevent it. He had not seen a case where it had been necessary to use a vaginal tampon, such as had been described by Dr. Mundé. With regard to dilatation he had not found it necessary.

Concerning the sharp curette, he had seen Dr. Sims use it many times, and had a set which Dr. Sims selected for him only a few years ago; they were inflexible, were essentially sharp instruments, and with them he could readily scrape off the mucous membrane.

As to laceration of the cervix in etiology of fungoid degeneration of the endometrium, he did not intend in his paper to lay much stress on it, although it was a recognized and an efficient cause.

Dr. Hunter was inclined to the opinion that, where hemorrhage occurred after curetting, all the fungosities had not been removed. For the removal of the usual fungosities he objected to the use of the sharp curette, as the blunt curette was quite sufficient. The return of the fungosities was an important consideration in connection with the after-treatment.

ORGANIZATION OF SECTIONS.

Dr. Putzel reported that the *Section in Neurology* had organized, and that the first meeting would be held at the Academy on Friday evening May 8th.

Dr. Hudson reported that the *Section in Practical Medicine* had organized, with Dr. A. L. Loomis, chairman.

APPOINTMENTS BY THE PRESIDENT.

The President appointed Dr. E. G. Janeway to deliver the *Anniversary Discourse* in November next; Dr. M. H. Henry to read a memoir of Louis Elsberg, M.D.; and Dr. D. B. St. John Roosa to read a memoir of James Lawrence Little, M.D.

The Academy then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, April 7, 1885.

W. J. Morton, M.D., President, in the Chair.

THE TREATMENT OF EXOPHTHALMIC GOITRE.

Dr. A. D. Rockwell read a paper on this subject. He had had experience in the treatment of fifteen cases of this disease, of which four had been reported in the New York Medical Record, vol. xvi., No. 14; six in vol. xviii. of the same journal, and one in the *New York Medical Journal* for June, 1881. Under the use of the galvanic current, mainly, six of these cases were either completely or approximately cured, two decidedly improved, one slightly benefited, while in two cases no results followed the most varied and persistent methods of treatment. The four remaining cases had never been reported. Other cases had been seen and treated by the author of the paper, but not with sufficient persistency to render them of statistical value. Dr. Rockwell considered that the prognosis in this condition was far more favorable than it was generally considered, and for this reason, and because the tendency was to reserve for final trial the form of treatment that is of primary importance, he was tempted to again call attention to the subject. Efforts in the management of these cases should be of a threefold nature: 1. Attention to diet and hygiene. 2. Internal medication. 3. Electricity. In some cases he had found that the most rigid and conscientious observance of certain fixed rules in regard to eating and drinking, and the avoidance not only of *excess* in every department of mental and physical hygiene, but the repressing of ordinary and legitimate emotions and passions, became absolutely essential. A bland, milk diet was to be generally recommended. Of all forms of internal medication that had been suggested, there were none that Dr. Rockwell's experience so entirely approved as the formula including iron, zinc, digitalis, and ergot. The therapeutical measure, however, which stands prominent, and to which all other forms of treatment must, as a rule, be but supplementary, is the constant current of electricity.

One of the most satisfactory cases of which he had knowledge, occurred in the person of a young lady aged twenty, referred to him by Dr. A. R. Carman and Dr. Van Santvoord. The eyes were unusually prominent, the goitre large, and the pulse from 140 to 160. The patient was weak, unable to take but little exercise, and the symptoms were in every way of a most aggravated character. The patient was treated from June 11, 1882, to March 29, 1883, a period of nearly ten months, and received in all sixty-nine applications of electricity. The result was a complete dissipation of every symptom, with the exception of a slight prominence of the eyes, which the parents thought might be congenital. Upon examining the case with her physician a short time since, Dr. Rockwell found no trace of the disease. If his results had been more satisfactory than those generally obtained, he would ascribe it to persistency and method. Another of the four remaining cases was sent to him by the late Dr. Sims. The three cardinal symptoms were present to a noticeable degree, the gland being enlarged to about the size of a hen's egg, and similar in shape. The pulse averaged only about 105, although under excitement it went up to 135. Under treatment with the occasional introduction of a needle, the pulse was reduced to the uniform frequency of 80, and the measurement around the neck over the tumor reduced from fifteen to fourteen inches. In a case sent by Dr. J. Chauveau, the benefit obtained, although decided, was much less satisfactory than in the two preceding cases; the pulse has been lowered some fifteen beats, and the goitre very much decreased, but symptoms of an asthmatic character have developed, complicating the case, and rendering the improvement less marked. The fifteenth and last case occurred in the person of a lady aged thirty-seven, and followed childbirth. When first

seen by Dr. Rockwell, the measurement around the neck was fourteen and three-fourths inches, the eyes slightly but distinctly protuberant, and an average pulse of 115. The health of the patient was exceedingly poor in many ways. This patient received fifty-two applications, with results almost equal to those obtained in the case first mentioned. Dr. Rockwell's method of treatment in Basedow's disease is to first place the cathode over the cilio-spinal centre, and the anode in the auriculo-maxillary fossa, gradually drawing the latter, after a few moments of stabile application, along the inner border of the sterno-cleiso-mastoid muscle until the sternum is reached. The second step in the operation consists in placing the cathode over the goitre and the anode in the region of the solar plexus. Variations in the method can be adopted according to the exigencies of individual cases, and the experience of the physician. In one case which resisted the usual method of application, immediate and permanent improvement followed the use of currents that were increased and decreased with exceeding rapidity by means of a rheostat.

Summary of results.—Of the fifteen cases that were persistently and steadily treated by Dr. Rockwell, electricity being the main reliance, nine were either completely or approximately cured, three decidedly improved, one only slightly benefited, while in two cases no appreciable result followed persistent effort.

Dr. Seguin asked why Dr. Rockwell placed the electrodes as described by him.

Dr. Rockwell replied that he placed the negative pole over the goitre because it was generally admitted that any absorptive processes were more energetically performed at the cathode than the anode. Still he did not wish to lay any special stress on this point. The main factor contributing to successful treatment was persistence on the part both of patient and physician.

Dr. Seguin had seen a few cases of Basedow's disease, mostly, however, in consultation. The method advised by him was the same as Dr. Rockwell's. But his results had been much less satisfactory, and in no case did he remember a perfect cure.

In cases of rapid pulse, associated or not with exophthalmos, he had for the past five years employed aconitia with very gratifying results. A progressive, and at length permanent, diminution of the pulse-rate had followed the exhibition of the drug.

One woman, aged fifty-five, who had come to him with a pulse of 160 and slight exophthalmos, had her pulse reduced to 85, after six or eight months' treatment. The subjective sensation of internal heat, and tremors, had at the same time disappeared. He generally gave the drug to the amount of $\frac{1}{100}$ of a grain for the twenty-four hours. The directions being to dissolve this quantity in a tumbler full of water, and take a mouthful of the solution for each dose. After one week the amount was increased to $\frac{1}{60}$ of a grain, taken in the same way. In one case he had given as much as $\frac{3}{100}$ of a grain in the same manner. He had also used the fluid extract in two-drop doses.

Dr. Weber related the case of a woman, fifty years of age at the time of her menopause, who had come under observation with slight exophthalmos and a pulse-rate of 146–160. There were subjective sensations of heat, but no measurable rise of temperature. In a comparatively short time this patient lost about twenty pounds in weight. But at the end of a year all these symptoms disappeared, and during the past four years had not returned.

Dr. Dana believed that there were irregular types of Basedow's disease, and that in many, galvanic treatment produced no marked results. Persistent bed-rest would then act better. He thought the purely neurotic type of the disease was always very difficult to relieve. But there was a second variety that might be called accidental or symptomatic goitre, and which might perhaps be a self-limited affection. It was to be remembered that such simple measures as a milk-diet had been reported to have resulted in a cure of the disease.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEBATE ON CHOLERA—CONCLUSION—SIR ANDREW CLARK'S LUMLEIAN LECTURES—MEETING AT THE COLLEGE OF PHYSICIANS.

London, April 7, 1885.

The debate on cholera at the Medical and Chirurgical Society was resumed at the last meeting and brought to an end. No fewer than twelve speakers took part in the adjourned discussion, which included, besides, the reply of the opener of the debate, Dr. George Johnson. Not much interest can be said to have been evoked by the adjourned debate, which, indeed, somewhat resembled the proverbial "wandering round and round Robin Hood's barn."

Dr. Heneage Gibbes defended Klein. Sir Guyer Hunter, of volunteer ambulance fame, maintained that Koch had shown that the comma bacillus stood in the relation of cause and effect to cholera. Dr. Pye-Smith discussed the pathology of the choleraic discharge, and referred to Moreau's experiments on section of the mesenteric nerves. Mr. Macnamara, after laying down that no epidemic is known to have originated outside British India, and stating that Klein's statements with regard to infection are at absolute variance with the conclusions of all previous workers, made the interesting remark that the comma bacillus corresponds to the characters of the cholera contagium as described by Parkes, viz., it is destroyed by acids, its life in water is very brief, and the conditions under which the water is placed must be of a certain kind. Dr. Heron returned to the bacterial aspect of the subject. He said that, from the beginning of the growth of the various comma bacilli, it was possible to distinguish Koch's bacillus from all the others. All the comma bacilli could be distinguished from one another. Koch and Klein, he said, were agreed that there was a comma bacillus peculiar to cholera, which was to be found nowhere else. Lewis's comma bacillus was different. Dr. Thin remarked that many people believed that the comma bacillus of Koch could be found in other diseases than cholera. He thought that Dr. Klein, or those who reported him, were responsible for this impression.

Several gentlemen spoke at some length on treatment. The President was almost alone in supporting the evacuant method, though he actively defended in his reply the views expressed in his opening paper. If mere words count for anything, Dr. George Johnson ought to have convinced all present, for he was prolix to a fault. He was evidently determined not to abandon, without a struggle, the theory which he has been diligently nursing for thirty years. Most of the speakers condemned the evacuant plan of treatment. Opiates, astringents, stimulants, intravenous injections of hot saline solutions, and the administration of nutrients, were all more or less favorably spoken of by the different speakers.

Sir Andrew Clark has lately been discoursing on "dry pleurisies" at the College of Physicians (Lumleian Lectures). He defines a dry pleurisy to be "such an inflammation of the pleura as issues in an exudation of lymph into the substance and upon the surface of the membrane, unaccompanied by an amount of serous effusion sufficient to yield physical signs conclusive of its presence." Sir Andrew Clark remarked that the existence of such pleurisies had been denied by some observers, and that some of the highest authorities in medicine were ranged on either side. Their influence, too, in originating secondary disease of the lung, had been hotly contested. The first lecture was almost entirely occupied in the narration of twelve cases, and as, to quote Sir Andrew's own words, his endeavor had been "to present them in their baldest objective forms," not even his elocutional powers could

succeed in making interesting such a catalogue of signs and symptoms, which therefore fell rather flat upon the audience. His opinion seems to be that "dry pleurisies" are by no means uncommon, but that they may seriously alter and destroy the substance of the lungs.

In his second lecture Sir Andrew made some important statements respecting the anatomy of the lungs. He criticised the accounts given by various anatomists, remarking that Klein's is, on the whole, the simplest and most accurate. Sir Andrew complained of the multiplication of distinctions and the unnecessary use of complex terms by writers on the subject. He then presented a simpler conception. "The primitive type of a lung," he said, "is a cylindrical tube, the sides and end of which are portioned out by delicate membranous septa into shallow cubical spaces, not communicating with each other, but only with the common lumen of the tube round which they are arranged." This idea he proceeded to elaborate in some detail. Those who only know Sir Andrew Clark as the busy physician may be somewhat taken aback at his boldly trenching on anatomical ground, but in pathological anatomy, at any rate, he is no tyro.

Sir Andrew Clark began his career in London as pathologist to the London Hospital. He came from his home to compete for this post, and while he held it was an indefatigable worker in the post-mortem room. He studied the anatomy of the lungs somewhat closely many years ago, and contributed the chapter on this subject to the late Dr. Herbert Davies's work on "The Lungs and Heart."

The meeting at the College of Physicians on Monday last was unusually well attended. A committee was appointed to report on the proposed publication in facsimile of the manuscript notes by Harvey which are now in the British Museum, the subject having been brought forward by Dr. George Johnson. Sir William Jenner delivered an address in which he passed in review the events of the past year which related to the College. He spoke of medical legislation and the failure of the Medical Bill. Referring to the new conjoint scheme of examination entered into by the two London colleges, he went on to speak of the question of a London medical degree. Sir William Jenner said the question was one which might well be entertained in connection with the new board, and he even went so far as to say that he thought the college might institute an inquiry into the best means of acquiring the power to grant degrees. Sir William Jenner, be it remembered, is a graduate of the existing University of London and a member of its senate.

OUR VIENNA LETTER.

(From our Special Correspondent.)

TREATMENT OF THE WOUND AFTER HYPOGASTRIC CYSTOTOMY—THE NEW ANTIPYRETICS.

VIENNA, March 25, 1885.

SUPRA-PUBIC cystotomy is at present the favorite operation among Vienna Surgeons for the removal of foreign bodies, stone, or tumors from the bladder. The method of after treatment is now undergoing discussion here. Professor Dittel, who is the strongest advocate of this method of operating, and has performed the operation the greatest number of times, insists on leaving the wounds in the bladder and abdomen both open and in drainage by means of the side position with the hips raised. In general he says the open treatment gives the best results. In forty-one cases where the bladder wound was sewn up only sixteen recovered. The only advantage of closing up the wound would be, perhaps, to shorten the course of the time of convalescence. This is only a possible advantage, which, even if it were certain, is not worth considering in so important an operation. A great disadvantage is, that in a short time the stitches become incrustated. Usually they ulcerate out before union takes place, and the urine then infiltrates the abdominal tissues with the worst results. Stitches are, therefore, at least entirely superfluous, and in most cases positively do great harm.

Professor Billroth also dresses the wound without closing it. Since he lost a patient, as he says, from stitching together the cut, he has given up entirely the use of sutures in this operation. However, the condition of the urine at the time of operating, and directly after, greatly influences the result. Urine often contains slightly poisonous properties, and there are times when a single drop will set up a phlegmon. Some cases of hypogastric cystotomy get along all right, and others—as far as can be seen exactly similar cases—end badly. He concludes that the bad result in these latter cases was due to some special infectious quality of the urine at that time. He was unable at present to explain it in any other way. Professor Billroth's mortality in this operation has been very high.

Dr. Ultzman usually stitches both wounds. The sutures in the bladder to a certain extent prevent the infiltration of urine into the surrounding structures. The stitches usually hold at least three or four days: union of the bladder wound does not take place primarily. Dr. Ultzman thinks it best to sew the cut surfaces in the bladder together, and leave open the abdominal wound. However, in an operation which I saw him make recently on a ten year old boy, he left both wounds open with the most satisfactory results. In all cases where sutured the interrupted silk sutures are used.

The reduction of temperature in febrile diseases by internal or external means has been the cause of much careful study and work in the Vienna clinics for the last two or three years. The result at which physicians have been aiming for the past quarter of a century, has been almost, if not quite, reached by the extensive and exact experiments and researches of the Vienna school of internal medicine. At least such results have been obtained, that to-day a febrile temperature can be reduced to any degree that is proper, and it can be done easily, rapidly, and without injuring in the slightest the vitality of the patient. The demand of to-day is for powerful antipyretics as internal remedies. They are remedies that do not affect the course of the disease directly, but simply, and solely reduce the temperature. According to Nothnagel they are never to be given under a temperature of 39.5, or in the early stage of a fever, as they will then obscure the diagnosis.

At present only the following drugs are considered here as antipyretics: quinine, thallin, antipyrin, and salicylate of soda. Of the two new remedies, antipyrin has been in use about a year. Thallin was discovered and first used about seven months ago by Dr. von Jaksch of Professor Nothnagel's clinic.

Quinine, says Professor Nothnagel, is the best, or perhaps better said, the oldest antipyretic in general use. He prefers to give it in the form of the bisulphate and in solution. He dislikes gelatine capsules and similar vehicles, as they have been found undissolved in the stomach two days after administration. He also gives the quinine in one large dose, not in divided doses: one and a half to two grammes (1.5–2) is the ordinary dose and is best given at seven or eight o'clock in the evening, so that its action begins at the time a normal fall of temperature usually takes place. Quinine reaches its greatest effect six to eight hours after taking. In some fevers, for instance, pneumonia, typhus, and septic fevers, it has little effect. In Carl Braun's wards, in puerperal fever antipyrin is much preferred to quinine or the other antipyretics. Salicylate of soda, to reduce temperature, is little used. Its antipyretic action is similar to that of quinine, except that the fall of temperature after salicylate of soda is more rapid, and the rise again also comes on sooner and is more rapid. It produces little or no sweating, and must be given in double the dose. Its action in acute articular rheumatism is specific and not

antipyretic. Kairin and resorcin are not used any longer here, probably because of their marked tendency to be followed by collapse.

Prof. Nothnagel says that thallin and antipyrin are very powerful, simple antipyretics, and extraordinarily good ones. Collapse rarely or never follows their use. He has very little choice between the two; the antipyretic effect from thallin seems to last a little longer, and the dose is smaller. Thallin is given in the form of a sulphate, usually in from two to five decigramme doses (2–5). The dose of antipyrin is about one gramme. The temperature begins to fall inside of an hour after giving these drugs. In one case of pneumonia, in the service of Dr. Bamberger, there was a fall from 40.5 to 38.6 within an hour from a quarter of a gramme of thallin. The temperature of pneumonia is especially susceptible to these two remedies, and there is hardly any fever that can resist them.

In the service of Dr. Hutler, where a large number of pneumonia cases have been treated by these antipyretics, the temperature has almost invariably been reduced to nearly normal. The mortality, however, was but slightly lower than when these drugs were not used. Often patients would die with a temperature that had been kept throughout the entire course of the disease below 37.5.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 12, 1885, *to April* 18, 1885.

BROWN, HARVEY E., Major and Surgeon. Leave of absence extended two months. S. O. 83, A. G. O., April 11, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 18, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
April 11, 1885.....	0	3	75	5	185	63	0	0
April 18, 1885.....	0	6	76	4	178	51	0	0
Deaths.								
April 11, 1885.....	0	0	12	3	22	31	0	0
April 18, 1885.....	0	3	12	3	21	22	0	0

THE LUNATIC ASYLUMS in Austria in 1881 numbered 27, containing 9,694 patients, or 42 per 100,000. Outside of the asylums the number of insane is 20,001, or 91 per 100,000 inhabitants. The per cent. discharged cured from asylums is only 6.7, against about 33 per cent. alleged to be cured in American asylums. The number of cretins in Austria is 15,151, or 69 per 100,000.

THE ACTIVE PRINCIPLES OF CANNABIS INDICA.—Various active principles have been obtained from cannabis indica, but none as yet which represent the entire virtues of the plant. A druggist, Bombelon, has separated three different substances: cannabin purum, cannabinon, and haschisch. Cannabinon is the only one which has given good results. Dr. Richter found in fourteen cases that it was a tolerably good hypnotic.

HOSPITALS IN AUSTRIA.—Austria has 159 public and 375 private hospitals, with a total of 29,167 beds. On an average, 1 out of every 82 of the inhabitants seeks hospital relief.

THE ONE REMEDY FOR AN INTERMITTENT PULSE, says Dr. Richardson, is alcohol. A great many people have felt this to be true before Dr. Richardson discovered it.

THE CLIMATE OF THE BERMUDAS has been recommended for lung diseases by a physician in this city, because, he says, "the onions make the breath so strong!"

HORSE-HAIR BOUGIES.—Dr. E. C. Franklin (*Medical Era*) has relieved an almost impermeable stricture by passing a horse-hair through, following it up with other hairs, and finally with bougies.

ACNE is sometimes due to urethral irritation according to Dr. S. Sherwell, who has relieved two cases with cold sounds.

DR. FORDYCE'S TREATMENT OF FEVER IN 1766.—The doctor commenced to teach medicine in 1766, as physician to St. Thomas' Hospital, London. He believed that all continued fevers, including typhus, typhoid, remittent, and yellow fevers, were irregular or so-called continued intermittents, made so by the intercurrence of some local or general inflammation. The remedies to be employed to convert them into regular tertian fevers were, in the first place, clearing the stomach and intestines from noxious matters contained in them, which were supposed to cause the inflammations and continued fever. He gave a mild emetic of ipecac in the evening and a moderate dose of rhubarb in the morning, and then ordered preparations of antimony, or ipecac, or "such other medicines as tended to produce appearances similar to those which take place in the crisis of intermittent fevers, especially perspiration. These remedies were given every four, five, or six hours, so as to act constantly but mildly on the system, *i.e.*, so as to produce coolness and moisture of the skin, but no nausea, or vomiting. These were continued several days until a perfect, or at least a longer remission, or even intermission, of the fever was produced, if only for six or eight hours. Then cinchona was quickly given in one or two drachm doses every hour, or half hour, or as much in quantity and as frequently as the stomach would bear. If the next exacerbation or paroxysm returned severely, the bark was omitted, and "the medicines producing symptoms similar to those which take place in the crisis of fevers, were recurred to until another intermission had been produced, when the cinchona was given again." Purging, excepting so far as to keep the bowels free from putrescent matters, was regarded as extremely hurtful in continued fever. Antimony was not to be given in doses larger that one-fourth or one-third grain, so as not to produce nausea, nor oftener than once in four hours. Warm drinks were given frequently, the patient was well, but not heavily, covered up in bed, and opium given to aid the action upon the skin, in doses of five or six drops of the tincture. or one-fifth of a grain of the powder, with five grains of aromatic powder to aid in preventing nausea. If the so-called continued intermittent fever withstood this treatment, Dr. Fordyce gave arsenic; or, if there was much diarrhœa, chalk mixture, or oxide of zinc, or acetate of copper. The preparations of iron he thought not as useful at first, as these other mineral remedies, but more useful afterward, when debility and anæmia were great. Iron he thought less useful in preventing the returns of the paroxysms of intermittent fever than arsenic, zinc and copper. He thought bleeding injurious. In Fordyce's time, the streets of London and all other large cities were not well graded, scarcely at all paved or sewered. Intermittents and all malarial diseases were

very common in cities, and typho-malarial diseases not infrequent. The morning remissions and evening exacerbations of all fevers were mistaken for attempts at intermission and the endeavor of nature to convert a continued fever into an intermittent, which should be encouraged and imitated by the judicious doctor. In this view his treatment was not irrational, and, in fact, with the exception of the use of antimony, which is now supplied by aconite, was very similar to that now employed in the treatment of typhoid fever. He even seemed to have some dim notions of the antipyretic action of Peruvian bark.

Psoriasis and Marriage.—The New York Dermatologists are divided on the question whether persons suffering from psoriasis should marry. Most are agreed, however, that if the disease is severe and continuous, it should be a bar to matrimony.

What a Tape Worm can Do.—Dr. B. O. Baker, of Kona. Hawaii. S. I., writes: "Mrs. W——, aged fifty-six, complained of pain that moved about in every part of the abdomen, in short, all the symptoms of a hypochondriac with amnesia and amaurosis. As a placebo, I painted the most painful part with a solution of menthol, ʒ j., Squibb's chloroform, ʒ iij. In a very short time after this a sensation, said to be "like the first motions of a child," was felt just above the bladder, and in the course of a few hours five inches of tape-worm passed away. The patient had been before many doctors in different parts of the world, but had not the slightest idea of tapeworm. Treatment: Chloroform (Squibb's) ʒ j., honey ʒ j. Teaspoonful every other hour (no fasting); then four compound cathartic pills. Result: The worm came away; the pains are all gone; the memory has returned, and sight fast improving.

Tartaric Acid covers the taste of quinine, senna, rhubarb, glauber salts. If bicarbonate of potash in solution be added to tartaric acid, cream-of-tartar will be precipitated; but if tartaric acid be added to a solution of bicarbonate of potash, a perfectly clear solution will remain until complete saturation ensue.

The Crow and the Country Doctor. (A medical fable.)—A flock of crows was much alarmed one day at the sight of a strange object in the midst of a field upon which they customarily fed. They at once called upon an old crow who practised his profession in those parts, and who made a specialty of corns, to give his opinion about the matter. The crow, having examined the object, shook his head, and said that it was a serious case, and that it was lucky he had been summoned so soon, though he should have been called earlier; and he would like the advice of his friend, the owl, who had had the benefit of travel abroad, and who was particularly skilful in cases which called for the steady use of the eyes. He would also like to have the frog, who was spending his summer vacation by a neighboring pool, and who had a wide reputation for his physiological knowledge, to see the case. The crow, the owl, and the frog met, and, having studied the object at a suitable distance, withdrew to the shade of a high wall in order to deliberate. The frog first opened his mouth, and observed that it was a nice case, which reminded him of a very curious experience that he had had with a piece of red flannel two summers before, when he received a severe contusion upon the centre of Goltz. After telling all about this very apposite event, the owl observed that such cases were extremely rare. He had, however, had two very much like them, the details of which he had forgotten. He then related some very humorous obstetrical stories, which much amused the crow. Having received these opinions, the crow thanked his colleagues for the valuable light they had furnished. He had himself been at first disposed to think the trouble a case of *terror corvorum*, or scarecrow; but the advice given reminded him now that the appearance in the cornfield exactly resembled a country doctor whom he occasionally met, and who, after practising medicine for forty years, was at present trying to live on what he had saved. The diagnosis was finally agreed upon, and reported to the anxious crows outside, who were much relieved. Moral: This story shows the profit that is got from consultation, and the lucrative nature of the practice of medicine.—*Boston Medical and Surgical Journal.*

Cocaine in the Opium-Habit.—Dr. Albert S. Adler, of Salmonville, A. T., sends us some extracts from an article by Dr. Wallé in the *Wiener Med. Blätter*, and from one by Richter, of Berlin. Both these writers believe in the efficacy of cocaine in the morphine-habit.

The Bright Tin Test for Sugar.—Dr. Wm. McCollum, of Brooklyn. N. Y., writes us in reference to the test for sugar described in The Record of March 7th, which consists in heating a drop or two of the suspected urine on a bit of bright tin. Our correspondent says: "The bright tin test which I have used for twenty-five years is not a crude test, but a nice one under a practised eye, and one so easily and quickly made. I call attention to the communication to correct an important error in the statement that 'if no sugar be present, it will be as distinctly shown by the characteristic odor of urine and by a bright, smooth, varnish appearance on the tin;' if he had added the words, of a golden color, he would have well stated what is shown when sugar is present in small amount. Any one can verify this statement by treating urine in this manner, containing no sugar, then add a grain or two of sugar to an ounce of urine and repeat the test. The characteristic odor of burnt molasses will only be noticed when considerable sugar is present. The evidence that sugar is present is apparent before the heat has carbonized the sugar. The bright gold-colored varnish upon the tin, noticed before an intense heat has burned the surface brown, is what should be especially noticed as evidence that sugar is present."

The New and Simple Ureaometer.—Dr. William H. Greene, of Philadelphia, Pa., writes: "The 'new and simple apparatus for determining the quantity of urea in the urine,' described by Dr. Charles A. Doremus, at a recent meeting of the New York County Medical Society, is essentially the same as that devised by myself and described in the *Comptes Rendus*, vol. xcvii., p. 1142, November, 1883. The description was republished in several German journals, and in the Philadelphia *Medical Times*, vol. xiv., p. 277. and is figured in the last edition of Da Costa's "Diagnosis." I am glad to see that it is favorably mentioned by Dr. Flint, as it has been manufactured and used in Germany since January, 1884. Dr. Doremus has simply removed the base from my apparatus, and bent the tube itself; but this very modification, as a form that might be home-made, I described before the Philadelphia County Medical Society in October, 1884. Either Dr. Doremus has knowingly claimed as his own an apparatus, to the invention of which I am entitled to unquestionable priority, or he has betrayed a lamentable ignorance of the recent literature of urine analysis."

The Button-Hook as an Eye-Opener and Eye-Holder.—Dr. C. G. Roehr, of Milwaukee, Wis., writes that he has for some time used the ring on a button-hook for the purpose of fixing the eye so as to allow of working at or on the cornea, as in extracting a foreign body lodged there, or even for fixing the eye in operating. By sliding any ring (of about three-fourths inch diameter) under the eyelid, and having a handle so as to press it firmly against the eye, it will hold or fix perfectly the eye, allowing one to work at ease. This device has enabled me to extract any foreign substance from the cornea without the usual difficulty of the patient winking or moving the eye. It might be well to make the ring wide (say a flange above and below) to hold up and down the lids.

International Congress of Hydrology and Climatology.—The study of hydrology, in its relations to practical medicine, and that of climatology, have made considerable advances in recent years, thanks to the progress made in the several sciences upon which these are more or less dependent. And now it is proposed to have an international congress for the encouragement and mutual improvement of those interested in these branches. The congress is to be held at Biarritz from October 1 to 8, 1885, under the presidency of Dr. Durand Fardel. The meeting is to be under the auspices of the Biarritz Association, assisted by the Society of Medical Hydrology of Paris and the French Meteorological Society. At the close of the congress there will be excursions to the various thermal and sanitary stations of the Pyrenees. Every one who makes declaration to that effect, enclosing at the same time a postal money-order for twelve francs ($2.50), will be considered an associate (*adhérent*) of the Congress. Applications for membership, accompanied by the necessary money-order, may be addressed to M. le vicomte de Chasteigner, treasurer of the Biarritz Association, Biarritz, France.

Flies and Cholera.—M. Marpmann has been conducting some observations which tend to show that flies may become carriers of micro-organisms. He found that the insects take in bacteria with what they feed upon, and that the microbes are not destroyed in their passage through the intestinal canal, but are found living in the excrement. This is a hint to the makers of fly-screens.

A New Journal of Pediatrics.—We have received the first numbers of the *Archivos de Medicina y Cirugia de los Niños*, devoted to the diseases of children, and especially to reports of cases treated in the Hospital of the Child Jesus in Madrid. The editor is Dr. Gonzalez Alvarez. The principal article in the first three numbers is on Resection of the Knee in Children, by Dr. Rivera y Sanz. There are, besides, several abstracts from Spanish and foreign journals, and a page or two of news items. A supplement to each number consists of several pages of a work on the Hygiene and Management of Early Infancy, translated from the French of Dr. A. Bourgeois.

Antipyrin.—Dujardin-Beaumetz thinks that antipyrin is a drug not without danger, even in the small dose of half a gramme. He grants that it may be the least dangerous of antipyretics, but says that its use ought to be limited to the phthisical, for, while it has a real action in their fever, it is, if not powerless, at least not trustworthy in other fevers.—*Progrès Médical*, March 7th.

Syncope and the Means of Averting it.—Dr. William J. Notley writes to the *Lancet* that in cases of syncope due to deficient cardiac action the application of heat to the head will prevent the access or revive the patient.

The Spleen becomes Larger in the Secondary Stage of Syphilis, according to recent investigations of Dr. Avanzini, of Innsbrück.

The Late Professor James L. Little, M.D.—At a special meeting of the Medical Board of St. Luke's Hospital, held April 8, 1885, the following preamble and resolutions were unanimously adopted:

Whereas, It has pleased Divine Providence to remove by death our beloved associate, Dr. James Lawrence Little, who was for eighteen years one of the most active members of our staff. Therefore, be it

Resolved, That in his death we mourn the loss of a friend whose personal worth and rare kindliness of feeling have endeared him to his associates in this Board, as well as of a surgeon who has won deserved distinction by enthusiastic devotion to his profession and successful achievements in surgery.

Resolved, That we extend to his family our heartfelt sympathy.

On behalf of the Medical Board,

Robert Abbe, M.D., *Attending Surgeon.*
A. Brayton Ball, M.D., *Attending Physician.*

The Physiological Action of Coca on Hunger, the Result of Anæsthesia.—Dr. Mans R. Vedder, of this city, writes: "Among the remarkable physiological properties ascribed to coca is the power to appease hunger and thirst. As I have not yet met with an explanation of the action of the drug in producing this effect, I venture to present a theory of it which I believe to be borne out by my experiments. These have been performed in greater part upon myself, and cover a period of four years, dating from the spring of 1881, when I received a quantity of the leaves of the plant from a source which left no doubt in my mind as to their genuineness and freedom from adulteration. Shortly after my initial experiments with the drug, I gave a quantity of my supply of leaves to Dr. Townsend and Dr. Chalmers, of the Union League Club; and in a conversation with the latter gentleman, held at the club soon afterward, I remarked to him that I believed coca possessed valuable medicinal properties not yet understood; adding, that it was my opinion it exerted a powerful influence upon the vasomotor system. Following the administration of a dose of the fluid extract, I have observed that thirst is immediately relieved, very much as it is sometimes relieved by putting shot into the mouth, viz., by an abundant flow of saliva. Soon there appears to be a loss of the sense of taste, or at least the mouth desire for food or drink ceases. This result also follows the administration of an infusion of the drug. If a dose of the extract or infusion be taken when the stomach is craving food, all desire for it ceases in a very short time. I have believed from the first that these effects result from a condition of anæsthesia. My belief in this was strengthened by a knowledge of the fact that the drug had been used externally for the relief of pain in rheumatism, neuralgia, and headache. The recent discovery, at Heidelberg, of the power of the active principle of coca to produce local anæsthesia, confirms me in the belief that the physiological property of the drug in arresting or mitigating hunger, is due to this effect alone. My views, briefly stated, are that coca taken internally in any of the ordinary forms, and administered by the mouth, produces by actual contact a degree of anæsthesia in the membranes of the mouth, throat, and stomach, varying with the quantity and strength of the preparation exhibited. The nerves of the mouth, throat, and stomach, naturally excited by hunger, are, by the influence of the drug, lulled, obtunded, or put to sleep; and, until the effect of the dose wears off, are incapable of exercising their ordinary natural perceptions and functions. If food be administered during this anæsthesia of the alimentary tract, there is no repugnance to it, but it excites neither appetite nor relish, and is eaten without desire or gratification; and is probably not even digested until the nerves of the stomach have recovered their normal condition. It is obvious that if this be true coca is not a substitute for food, that is, is not in itself nourishment. Indeed, there are many proofs that it is not. Those addicted to its use are emaciated. Dr. Pöppig, in his travels in Chili and Peru, speaks of the natives of South America who indulge in it as 'the victims of a most pernicious habit;' and likens the intoxication produced by it to that following opium. 'As the indulgence is repeated, the appetite for it [the drug] increases, and the power of resistance diminishes, until at last death relieves the miserable victim.' In an article published in the "Journal of the Royal Geographical Society," 1854, coca is alluded to as a 'poisonous narcotic;' and it is referred to by other writers as occasioning, when taken in excess, 'tremor in the limbs, and even a gloomy sort of mania.' In my own case it produced exaggerated dreams, similar to those induced by haashish.

Fatal Chicken-pox.—Two fatal cases of chicken-pox, one reported by Dr. G. W. Rachel, in the *Archives of Pediatrics* for April, 1884, the second by Dr. J. V. Wichmann, of Copenhagen, in the *Nordiskt Med. Arkiv*, xvi., No. 20, show that varicella is not always the mild disease which is its general characteristic.

The Medical Record

ATROPIA AS A REMEDY IN ETHER-NARCOSIS.

BY R. W. AMIDON, A.M., M.D.,
NEW YORK.

THE question has often presented itself to my mind, "Are the methods of meeting the alarming effects of anæsthetics sufficiently defined and sure to reflect credit on our science?" In my opinion they are not.

While, among published cases, ether very rarely kills, still every practitioner will, sooner or later, see alarming symptoms occur during its administration.

I think nearly all practitioners will agree with me when I state it as my conviction that sudden death from ether generally occurs in the third stage of anæsthetization, that of ether-narcosis—and also that the cause of death is a combination of asphyxia and syncope; the failure of respiration being more prominent and *primary*, the failure of the heart being less prominent and secondary. Death has been said to occur at the commencement of the inhalation from asphyxia caused by spasm of the glottis and a tetanoid condition of the respiratory muscles, including the diaphragm, but of such extreme rarity are these cases they may be wholly disregarded. Early and sudden death from syncope without premonitory symptoms, such as occurs from chloroform, has been reported but very rarely, and probably it never occurs unless there be organic disease of the heart. With the remote and infrequent consequences of the inhalation of ether—bronchitis, pneumonia, or gastro-enteritis—the present paper has nothing to do.

There are circumstances which render it difficult to limit the effects of the ether. The operation may be unexpectedly prolonged, it may necessitate a position detrimental to free breathing, the vital resistance of the patient may be diminished by vicious habits, exhausting disease, hemorrhage, shock, cold, cardiac or pulmonary lesions. In these, and many other ways, to say nothing of carelessness on the part of the anæsthetizer, more ether than is needed is given, and the stage of ether-narcosis supervenes. The operator notices a deepening color of the blood, which also flows less freely. He stops and finds that the skin has a dusky pallor, and is cool and moist; the pulse is weak and not very fast; the temperature of the body is subnormal, and the respiration is very stertorous or shallow, and almost imperceptible.

Symptoms referable to the	Third stage of asphyxia.	Stage of ether-narcosis.
Skin.	Bluish pallor; cool and moist.	Bluish pallor; cool and moist.
Arterial tension.	Lowered.	Lowered.
Heart.	Very slow and gradually weakening.	Not fast nor very weak.
Temperature.	Subnormal.	Subnormal.
Respiration.	Gasping; deep, slow, and irregular.	Slow and shallow; regular.
Motility.	General relaxation disturbed by general tetanic convulsions.	General relaxation.
Reflexes.	Abolished.	Abolished.
Sensibility.	Abolished.	Abolished.

Ordinarily, a simple withdrawal of the ether with traction on the tongue or lifting the jaw forward will inaugurate free respiratory movements. Sometimes it is not alone a mechanical impediment but a benumbing of the respiratory centre that exists, and a condition of "modified asphyxia" ensues, whose symptoms differ somewhat from those of true asphyxia, because of the effect of the anæsthetic circulating in the blood.

The train of symptoms in asphyxia depends first on the irritating effect of carbonic acid gas on the nervous centres. In this way are produced the initial convulsions, the dyspnœa, and the strong, slow pulse. This irritation is excessive, as the violence of the convulsions and the forced respiratory acts show.

As the respiratory centre becomes exhausted, it is at long intervals only that the CO_2 in the blood can stimulate it to action, hence the respirations are infrequent, irregular, and gasping. The inhibitory centre of the heart is still irritated by the CO_2 and the pulse remains slow. At the same time the muscle of the heart feels the want of oxygenated blood and the pulse gets weaker.

During ether narcosis asphyxia is seldom complete and the anæsthetic deadens the effect of the CO_2 on the respiratory and cardiac centre, hence the respiration, still slow, is shallow and regular, while the stimulating action of the ether on the substance of the heart tends to make the pulse stronger and more rapid than in the corresponding period of pure asphyxia.

If means of resuscitation avail nothing, the skin loses some lividity, may assume an ashen pallor, and is cool and clammy. Respiration, if present, is slow and shallow. Râles are heard in the trachea and large bronchi, while all over the lower and posterior parts of the lungs, finer râles point to the presence, in the smaller bronchi, of mucus or œdematous fluid. The pulse becomes very weak, perhaps imperceptible at the wrist. Involuntary evacuations may have taken place. The respiration becomes slower and shallower and finally stops, while the heart beats on feebly for a short time.

In a person dying thus the chief lesions are: a venous congestion of all the viscera, provided no large hemorrhages have occurred; a fulness of the large venous trunks and distention of the right side of the heart; the trachea and larger bronchi contain reddish fluid, some of which is undoubtedly mucus secreted in the mouth and throat and inspired, while a frothy œdematous infiltration may occupy the base and back of both lungs, or perhaps, in varying degrees, involve the whole of both organs. This is essentially the pathological anatomy of asphyxia and is brought about in the following manner: The vapor inhaled gradually displaces a certain amount of air from the lungs and oxygen from the blood. The capacity of the lungs for holding air, and the consequent oxygenation of the blood, is still further encroached upon by a gradual filling up of the large air-passages with bronchial mucus, the secretion of which is increased by the irritating nature of ether vapor. At first this hypersecretion is coughed up, but soon, through benumbing of the respiratory centre, the secretion fails to excite expulsive efforts and accumulates. This heightens the asphyxia and at the same time removes the compensating factor of dyspnœa. The heart, thus supplied with poorly oxygenated blood, weakens, a passive hyperæmia of the lungs sets in, which may result in a more or less marked pulmonary œdema, which, with the progressively failing heart, rapidly proves fatal.

These deductions, partly theoretical, partly practical, drawn from man, are fortified by similar results obtained by experimentation on animals.

When the animal is fully anæsthetized, an artery is connected with the mercurial manometer of a modified kymograph of Ludwig. By this means can be graphically represented, the blood-pressure, the frequency and force of the heart, and sometimes the respiratory movements. When fully anæsthetized the visible mucus membranes are rather turgid and moist, involuntary evacuations may occur, there is general relaxation, the reflexes and general sensibility are abolished, the respirations are deep, regular, and of about normal frequency, the pulse is fast, full, and strong, and the blood-pressure is about normal.

If the inhalation be continued the respirations soon get slower and shallower, and at once a change, which is the lethal change, commences. It consists of a rapid fall of arterial tension and more delayed indications of a failing heart.

After respiration finally ceases there immediately ensues a rapid and progressive weakening and slowing of the heart and a fall of blood-pressure, so that, in from thirty seconds to two minutes after breathing ceases, the weak and slowly-beating heart stops, the blood-pressure having fallen to a minimum.

The accompanying schedule gives, in tabular form, the results of such an experiment:

	Time.			Arterial pressure in mm. of mercury.	Force of heart in mm. of mercury.	Pulse per minute.
	Hrs.	Min.	Sec.			
	4	1	00	122.0	18.0	160
	0	2	00	122.0	18.5	155
	0	3	00	120.0	19.0	170
	0	4	00	112.5	19.0	165
	0	4	35	104.5	19.0	160
	0	5	00	92.0	16.5	160
*	0	5	42	79.0	14.5	160
	0	5	50	66.5	12.5	150
	0	6	00	60.0	12.0	145
	0	6	10	51.5	10.5	145
	0	6	20	43.0	8.5	140
	0	6	30	37.5	7 5	130
	0	6	40	35.0	6.5	120
	0	6	50	33.5	6.5	110
	0	7	00	32.0	6.5	110
	0	7	10	30.5	5.5	110
	0	7	20	28.0	4.0	110
	0	7	30	25.5	2.5	110
	0	7	40	24.0	1.5	100
	0	7	50	20.0	0.5	100
†	0	8	00	20.0	0	0

* Respiration ceased. † The heart stopped.

In this case it will be seen that the heart continued to beat with diminishing frequency and force, and with constantly falling arterial tension for over *two minutes* after all respiratory movements ceased; and it is my impression (deduced from repeated trial) that, within at least the first ninety-eight seconds, insufflation would have saved life.

The post-mortem appearances of animals so killed resemble those seen in man, viz., venous engorgement of the viscera, over-distention of the venous trunks with dark, semi-fluid blood, culminating in a tremendous distention of the right auricle and ventricle; the left auricle and ventricle are nearly or quite empty, the lungs are somewhat congested, and the bronchi generally contain some frothy, bloody serum. The probable mode of production of these lethal symptoms is as follows:

The fall of blood-pressure is caused by—

1. Exhaustion of the vaso-motor centre by accumulation of CO_2 in the blood.

2. Gradual but almost complete emptying of the left side of the heart and arteries into the veins and right heart.

3. Weakening of the heart.

The weakening of the heart is caused by—

1. Over-distention of the right side of the heart from obstruction of the pulmonary circulation by infrequent and shallow respiratory movements.

2. Malnutrition of the muscular substance of the heart, which is supplied with (*A*) a diminished quantity of blood because of (*a*) the slowness of the beat, (*b*) the low blood-pressure, (*c*) the emptiness of the arteries; (*B*) a poor quality of blood (a large percentage of CO_2).

The slowing of the pulse is caused by—

1. Stimulation of the inhibitory centre by CO_2.

2. Unilateral over-distention of the heart.

3. Probable depression, by ether, of the motor functions of the accelerator centre for the heart.

Taking into consideration the prominence of the failure of respiration, it is remarkable that more attention has not been paid to its re-establishment in the treatment of ether-narcosis. It is true that artificial respiration has for years been held as an almost unfailing remedy, and its reputation has been well deserved. The chief stain on its record is that roundabout ways of maintaining it (as electricity, etc.) have been at various times advocated to the exclusion of simple mechanical means or insufflation.

Wood[1] says: "When artificial respiration is maintained, animals bear an enormous amount of this drug without cardiac failure."

Ringer[2] says: "Ether, therefore, induces very little paralyzing effect on the ventricle. In fifty-minim doses it accelerates and somewhat weakens its action, but, from the great acceleration, the ventricle must perform more work than before the addition of ether."

At the same time, I think clinicians have been apt to under-estimate the respiratory failure and over-estimate the circulatory failure, thus relying on cardiac stimulants to the neglect of artificial respiration. What so common as to see the syringe whipped out and a hypodermic injection of ether, alcohol, or ammonia given.

What more illogical than to suppose that the administration of a cardiac stimulant will excite to contraction an over-distended right heart unless the cause of that over-distention, *i.e.*, the shallow and infrequent respiratory movements, is removed? Again, is it not irrational, when a patient is overwhelmed with one cardiac stimulant, to throw into his circulation, not an antagonist, but a synergist? Bartholow says: "It is, however, very questionable whether the administration of alcohol or one of its derivatives can be useful in a condition of things brought about by an anæsthetic of alcoholic origin. The author believes, indeed, that serious mischief is done by this practice in cases capable of resuscitation."

Of all remedies subcutaneously injected probably alcohol is used most, and no one will deny that ether and alcohol are cardiac stimulants of very great similarity, and that ether-narcosis and the condition known as "dead drunk" are very similar. I am not prepared to deny that restorative effects follow and seem to be due to the administration of these cardiac stimulants, but it is my opinion that the improvement is due *more* to the simultaneous withdrawal of the ether, the admission of more air, and other procedures looking toward improvement in the breathing.

Having in my mind the illogical use of purely cardiac stimulants it seemed to me there was much rather a need of a respiratory stimulant, and I thought that belladonna filled the indications present better than any one drug, it being principally a respiratory stimulant but also in certain doses a cardiac stimulant too. I thought the field thus opened up was new, but on going over the literature of anæsthesia carefully I find that it has attracted some attention before, but for some reason has never been thoroughly studied or put to practical use.

Bartholow, in a prize essay entitled "The Physiological Effects and Therapeutic Uses of Atropia and its Salts,"[3] says: "The subcutaneous use of atropia before the administration of chloroform, lessens the dangers of paralysis of the heart and of respiration." He says nothing of its being similarly used in ether-narcosis, and in his "Materia Medica and Therapeutics," New York, 1884,

[1] H. C. Wood: Therap., Mat. Med., and Tox., 4th edition, p. 288.
[2] Sidney Ringer: The Influence of Anæsthetics on the Frog's Heart, Practitioner, 1881, xxvii., p. 15.
[3] Transactions of the American Medical Association, vol. xv., 1869, p. 672.

he in only one place refers to the remedy he studied so many years before. On p. 714, in the "clinical index," as an antidote to chloroform taken by the stomach, he mentions atropine among other remedies.

In the New York MEDICAL RECORD, 1882, xxii., p. 274, an anonymous writer speaks of giving with good result first .0008 and then .001 of the sulphate of atropia to a patient suffering from the coma and collapse of a combined administration of morphine and ether.

Lister[1] says, when speaking of the toxic effects of chloroform inhalation: "Atropia is a most powerful respiratory and cardiac stimulant, rapid in action, and, by the hypodermic method, readily introduced. Its reaching the nervous centres governing these functions in cases where the circulation is reduced to a minimum must, however, be considered problematical. There is no question that it should be administered if at hand, but its action as a preventive of accident is without doubt more reliable."

Reeve[2] says, when speaking of the dangers attendant upon the administration of ether: "As a preventive of accident atropia is, without doubt, far more reliable than as a means of rescue when it has occured."

The antagonism between ether, with its narcosis and asphyxia, and belladonna or atropia is seen at a glance by referring to the subjoined table:

Symptoms referable to the	Ether-narcosis and asphyxia.	Poisoning by atropine.
Skin.	Bluish or ashen pallor; cool and moist.	Suffused perhaps; scarlet; hot and dry.
Mouth and throat.	Moist or full of mucus.	Very dry.
Intestines.	Relaxed; perhaps involuntary evacuations.	Increased tonicity and peristalsis.
Urine.	Normal amount; perhaps involuntary evacuation.	Diminished in amount; retained.
Arterial tension.	Lowered.	Elevated.
Pulse.	Not very fast; weak.	Very fast; strong.
Temperature.	Subnormal.	Slightly febrile.
Respiration.	Slow and shallow; perhaps stertorous.	Rapid and deep.
Pupil.	Perhaps (?) contracted.	Dilated to a maximum.
Motility.	General relaxation.	Restlessness.
Reflexes.	Abolished.	Normal or heightened.
Sensibility.	Abolished.	Normal or heightened.
Consciousness.	Lost; a condition of profound coma.	Insomnia; excitement or even wild delirium.

To determine whether this antagonism is real or only theoretical, several sets of experiments were necessary; they were performed chiefly on adult healthy cats, which, so far as I know, have no idiosyncrasy to either ether or atropine.

When cats are first atropinized, I have found that they are readily brought under the effects of ether, and that the atropine in nowise detracts from the anæsthetic effect of the ether, but seems to secure the animal considerable immunity from its narcotizing effects. Cats being fortified by a preliminary dose of atropine take more ether, and for a longer time without depressing effects than others. This antagonistic effect is still better demonstrated when the ether is given first, as the accompanying experiment will show.

A cat was fully anæsthetized, and the inhalation was kept up by means of a tracheal tube. Ordinarily a cat will die in from two to seven minutes when treated in this way. When the pulse had been reduced to 120, the respiration to 12, the blood-pressure to 50 mm., and the force of the heart to 8 mm., in short, when the stage of modified asphyxia seemed imminent, .012 sulphate of atropia were given hypodermatically. There followed an immediate slight rise in arterial tension. The administration of concentrated ether vapor was continued uninterruptedly for twenty minutes, when the animal remaining in about the same condition, the ether was removed. The animal showed signs of returning consciousness about fourteen minutes later. It will be seen in this case that concentrated ether vapor was given continuously for half an hour, while usually an administration for five minutes, under like circumstances, proves fatal.

	Profoundly narcotized, atropine .012 given.	Twenty minutes later, ether continued.
Pulse	120	110
Respiration	12	20
Blood-pressure	50 mm.	36 mm.
Strength of heart	8 mm.	6 mm.

From this and many similar experiments it would seem that the asphyxiating effect of ether is almost indefinitely postponed by the timely administration of a large amount of atropia.

The crucial test of the value of atropia depended upon the results of experiments to determine whether atropine, when given after respiration has stopped but the heart was still beating, would initiate respiratory movements and restore life. The following is one of these experiments given in detail:

With a full-grown cat the administration of ether was commenced at 2:45, at 2:50 she was etherized; at 2:55, pulse, 232; respiration, 48, and the animal was connected with the kymograph. At 3:04 the pulse was 246; respiration, 36; blood pressure, 160 mm., and the respiratory curves were well marked. At 3:08 the respiration had stopped entirely, and apparently, finally, the pulse was 234, and the blood-pressure was 140 mm. In twenty seconds there commenced a rapid fall of blood-pressure, reaching at 3:8:33 as low a point as 82 mm., the pulse being 240.

When the blood-pressure had fallen to about 100 mm. an injection of .006 sulphate of atropia was given, and the ether removed. The blood-pressure in a few seconds rose to 134 mm., having fallen as low as 82 mm. Fifty seconds after the injection of atropine respirations commenced, at first shallow, but in ten seconds more they became quite regular and deep and 36 per minute. The blood-pressure was 128 mm., and the pulse 258. At 3:11 the respirations were very deep and 36. Blood-pressure 130 and pulse 246. At 3:15 respirations very deep and 18; blood-pressure, 122; pulse, 258. At 3:21 the animal showed signs of returning consciousness; respiration, 36; pulse, 288; blood pressure. 120. Recovery was perfect, and the animal had to be killed by severing the medulla.

The results of my experiments warrant the assertion that atropine, while it does not impair the anæsthetic power of ether, lessens its asphyxiating tendency in a marked degree; also, that when the stage of asphyxia has commenced, the respiration has ceased, and the heart is failing, a timely large dose of atropia may save life, and we may even hope that, with other means, it may be powerful in the treatment of suspended animation.

In conclusion I will submit my suggestions as to the proper treatment of ether-narcosis as deduced from my experience and experiments. To avoid as much as possible the depressing effects of anæsthetics, which, I claim, are present in varying degrees in all cases, be careful to have the patient, particularly his extremities, warmly protected and, if necessary, warmed by hot bottles.

If alarming symptoms occur it must be remembered that the condition is generally one of depression, and hence stimulating, not depressing, remedies are indicated. For this reason the cold douching and slapping with cold wet towels should be avoided. Hot applications are just as exciting and devoid of danger.

If during the later stages of anæsthetization the respiration becomes embarrassed, the pulse begins to fail, and other alarming symptoms occur, take off the ether, draw the tongue and jaw forward and, if the respiration do not improve *at once*, give hypodermatically .002 of the sulphate of atropia and apply heat to the limbs and over the heart. If improvement does not occur in two minutes repeat the dose.

[1] Holmes' System of Surgery, American edition, vol. iii., article on Anæsthetics by Joseph Lister, Esq., revised by J. C. Reeve, M.D., p. 548.
[2] Loc. cit., p. 556.

If the respiration suddenly or gradually ceases, and neither lifting the jaw forward nor any other simple procedure starts it again, commence *mechanical* artificial respiration *at once*, the method of Sylvester being probably the best; admit fresh air freely. Have .003 of the sulphate of atropia given hypodermatically at once. Order hot applications to the extremities and precordial region. If a faradic battery be handy and in order, one electrode might be placed on the cervical spine and a strong current be applied diffusely over the chest with a wire brush. Even if the pulse disappears attempts at resuscitation should not be abandoned, the artificial respiration being the most important. The dose of atropia may be repeated if signs of recovery do not begin to manifest themselves in a minute.

I am of the opinion that free venesection would be of great service in some cases where the subject be plethoric and no large hemorrhage has taken place. My reasons for so thinking depend first on the fact that, on post-mortem examination of men and animals dying of ether-narcosis, venous engorgement and distention of the right heart is found; and secondly on the fact that I have repeatedly seen the heart in animals apparently dead of ether-narcosis, commence to beat again after a free incision in the liver (from which the venous blood will actually spirt) or a section of some large venous trunk or an incision into the distended right heart itself.

A CASE OF
PRIMARY EPITHELIOMA OF THE LARYNX.

Tracheotomy—Death Ten Months Later—Autopsy—Remarks.

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

Although cancerous disease of the larynx is not of rare occurrence, it is not often that opportunity is given for studying the development of a malignant laryngeal growth of the above variety from its very inception to its final inevitable termination. For the reason that the following history is complete, and because the case presents incidentally several instructive features, it has seemed worth while to place it on record.

John B——; Ireland; aged fifty; married; porter. The patient applied for treatment at the Throat Clinic of the College of Physicians and Surgeons, New York, October 15, 1882, and gave the following account of himself: Had always enjoyed excellent health; was not aware of any heredity; had been strictly temperate in the use of alcoholics, and regular in his habits; was a moderate smoker; gave no evidence whatever of any acquired constitutional taint. During the month of August, 1882, while employed as gatekeeper on the Elevated Railroad, first noticed a slight hoarseness of voice. This increased slowly, and soon began to be attended with a mild laryngeal cough. Soon afterward began to lose strength, appetite, and flesh.

When first examined, two months after the beginning of these symptoms, the patient appeared to be a fairly well-nourished man, of medium height and build, light complexion, and good intelligence.

Laryngoscopic examination, made with some difficulty by reason of a marked hyperæsthesia of the pharynx, revealed a condition which differed little from an ordinary chronic laryngitis. Both vocal bands were congested and thickened, the congestion extending throughout the whole interior of the larynx, but being most pronounced upon the left false cord, which was also slightly enlarged and prominent.

Examination of the chest showed physical signs of phthisis, first stage, at apices of both lungs.

By the middle of December following, the above-mentioned enlargement of the left false cord had progressed decidedly, and its surface, from being smooth and natural, began to be nodulated and uneven. This continued to such an extent that the presence of a new growth in the larynx, long before recognized, and for some weeks suspected to be of a malignant type, could no longer be doubted. From this time it developed with increasing rapidity, extending both above and below the left vocal band, but confining itself to that side of the larynx, while its surface began to break down and to form extensive ulcerations, which, irregular in outline and bathed in grayish yellow pus, presented the appearances characteristic of cancerous disease. Moreover, no beneficial results had been gained from the active internal administration of iodide of potassium, so that the possibility of its being specific was excluded. From the peculiar location of the growth its removal by endo-laryngeal operation was impossible. Meanwhile, with the exception of aphonia and a slight cough, the symptoms common to laryngeal cancer—namely, dysphagia, pain on external pressure, reflex pain in the ears, enlargement of the cervical lymphatic glands—were all wanting.

There was, however, a distinct external enlargement over the region of the left thyroid cartilage. During the next two months the progress of the case was unmarked by anything more than the gradual extension of the tumor, and the progressive deterioration in general condition of the patient. Early in February dyspnœa suddenly developed and soon became so urgent as to call for tracheotomy. The question of a partial extirpation of the larynx had, of course, presented itself. It was deemed prudent, however, to delay decision as to the latter operation until the trachea had become accustomed to the presence of the tube, and until the precise nature of the growth had been determined. The condition of the larynx at this time was as follows: erosion of the epiglottis; extensive ulceration of the left arytenoid prominence; destruction of left false cord and of left vocal band; involvement of the mucous membrane covering the left half of the cricoid cartilage, and of the first two rings of the trachea; while, externally, the region over the left thyroid cartilage was much enlarged. Owing to the inaccessible position of the morbid processes, and the importance of the structures involved, it was impossible to secure a specimen for microscopic examination. From its gross appearance, however, it was apparently epitheliomatous.

It was decided to operate at once, first performing tracheotomy and then continuing with the operation of extirpation should the conditions warrant that course. There were present at the time of the operation Drs. Cleveland, W. T. Bull, Lefferts, Nelson H. Henry, Hitchcock, and Beverley Robinson, of New York, and Dr. John H. Lowman, of Cleveland, O. Tracheotomy was performed as low down as possible, in order to facilitate any future attempt at extirpation. The tracheal rings were extensively ossified, and, on opening the trachea, they were found to be so resistant that a space large enough to admit the tracheal tube was exsected, instead of dependence being placed upon a simple incision into the anterior tracheal wall. Upon opening the trachea it was found that the disease had extended downward as far as the third ring. Its progress, however, seemed absolutely confined to the left side. The thyroid body was large and prominent, its isthmus lying over the lower aspect of the larynx. Had it seemed advisable to extirpate the larynx at a subsequent operation matters would have been greatly facilitated by dividing and tying the thyroid isthmus at the time of the tracheotomy. By a majority of those present it was deemed undesirable to proceed to extirpation of the larynx until the precise histological nature of the growth had been ascertained. Unfortunately, as had been from the first feared, it proved to be a true epithelioma.

The condition of the lungs, too, had become rapidly worse, so that the phthisical process was well advanced on both sides. Immediate present relief was afforded by the introduction of the tube, and recovery from the oper-

ation was rapid and without accident. A marked improvement in the general condition of the patient soon became apparent. He was able to swallow at this time with but little difficulty, and the tube was easily managed and but a slight annoyance. The larynx also underwent a remarkable change for the better, for, through the influence of the rest afforded by the tube, the respiratory movements of the glottis being of course abolished, the tumefaction subsided, the ulcerations ceased to extend and became to a considerable degree healed, and even the external enlargement over the thyroid became smaller and less prominent.

The disease was thus held in abeyance until about the middle of July, when, the weather becoming very warm, the patient began at once to run down. The deterioration in his condition was progressive, although more positive the warmer the weather. On my return to the city in October a laryngoscopic examination showed extensive and deep ulceration of the epiglottis, both arytenoids, and the whole interior of the larynx, and extending downward into the trachea as far as the tube, or, about four rings. The external tumor was but little more prominent than it had been four or five months before. A comparative condition of ease was maintained by the free administration of opium. Dysphagia was severe, but was almost entirely relieved by the use of the small stomach tube. Against this, however, the patient took a violent prejudice, on the ground that he had become too ill to desire to prolong his life by artificial means, so that, after a fair trial, its use was discontinued. Finally, after becoming so weak and exhausted from inanition that it seemed as if life could hardly be sustained from hour to hour, he fell into a state of semi-coma, and having lingered thus for two weeks, finally died.

Autopsy, forty-eight hours after death.—Body emaciated; rigor mortis marked; no œdema; tracheotomy tube *in situ*; old tracheotomy wound immediately above episternal notch. Extending from hyoid bone to tracheal wound, and laterally about two inches on each side of the median line, is a well-defined, hard, and immovable swelling, through which, by palpation, the outline of the larynx is imperceptible. On extending the tracheal wound upward to the lower border of the hyoid bone the whole cavity of the larynx is exposed and found to be distended with a decomposed, pultaceous mass of cancerous matter, which seems to extend upward to the base of the tongue, backward to the œsophagus, which it partly involves, and downward into the trachea to a point indefinitely below the tracheal wound. On careful examination of this mass with the point of a scalpel it is found that the cartilaginous structures of both trachea and larynx have been so extensively disorganized as to be unrecognizable, the rings of the former being represented by an occasional spicule, of bony consistence, while in place of the cartilages of the latter are found two or three thin osseous plates, in no case more than half an inch in diameter, evidently the remnant of the thyroid and cricoid cartilages. To remove the specimen is, under the circumstances, impossible. Thorax: Advanced phthisis in both lungs. Other organs not examined.

In reviewing the above record, the first feature of especial interest is the marked absence of early symptoms of malignant disease of the larynx as generally met with and described. Beginning apparently as a catarrhal laryngitis, and associated with pulmonary phthisis, there were no reasons for regarding the case as unusual until, it was made evident that the laryngeal lesion was unilateral, and even then some time elapsed before appearances suggestive of serious trouble were developed. With regard to the operation of tracheotomy, several advantages arose from opening the windpipe at the lowest point possible: diseased structures were avoided and the wound was made in normal tissue, so that it healed quickly and without accident; the upper part of the trachea was not disfigured, and thus rendered less manageable for the adjustment of an artificial larynx, had extirpation been performed; and, finally, the extension of the growth was not hastened by the irritation caused by too close proximity of the tube. The device of exsecting a portion of the anterior tracheal wall a little larger than the diameter of the canula rendered the re-introduction of the tube much easier, and its presence much less uncomfortable. Division of the thyroid isthmus, as before suggested, would not have been difficult of performance at the time of the tracheotomy, although had extirpation been afterward attempted its size and position would have made it, in all probability, a hindrance and a source of troublesome hemorrhage.

The extraordinary amelioration of the laryngeal condition which followed the tracheotomy was the most striking and perhaps the most useful lesson to be derived from the case. In an able and highly original article on "Ulcerative Phthisical Laryngitis, its Nature, and the Value of Tracheotomy in its Treatment," published in the *American Journal of the Medical Sciences*, April, 1879, the writer, Professor Beverley Robinson, of this city, advocates the propriety of tracheotomy in suitable cases of laryngeal phthisis, for the purpose of securing rest, and has, since that time, had gratifying results in cases similar to those described in his paper. Although prepared by a knowledge of his experience for some improvement in the present case, similar on account of the extensive ulceration which existed, the suspension of the respiratory movement of the glottis and the consequent rest to the diseased parts produced changes for the better which were far greater in duration and degree than could reasonably have been expected.

Extirpation of the larynx in this case was unquestionably contra-indicated; first, because of the almost uniform failure of that operation in epitheliomatous disease of the larynx; and secondly, on account of the advanced condition of pulmonary phthisis which existed. The greatest possible amount of relief to be gained from extirpation could not, as matters resulted, have equalled the fortunate effect of the simple tracheotomy.

Again, the value of the process of feeding by means of a tube of small calibre, introduced a short distance into the œsophagus, as described by the writer in the *Philadelphia Medical News*, June 7, 1884, was clearly demonstrated.

A not unusual feature in these most unhappy cases is the mode of death, by inanition, in which it oftens happens that life is prolonged for days, or even weeks, after the period set by the attendant as its probable extreme limit.

The condition of the larynx found post mortem afforded a remarkable instance of the destructive power of the disease upon every tissue which came in its way.

Finally, the inevitable question presents itself, Is it desirable, in such cases, to prolong the patient's life? In the present instance dyspnœa developed suddenly in February. Had tracheotomy not been performed death must have resulted in a few days. Of course, the duty for its performance was imperative. The patient, however, was a remarkably conscientious, practical, and logical thinker, and he himself decided to enjoy the probable respite likely to be afforded by the operation and take the risk of future consequences. The result of the operation was almost six months of comfortable existence. This, on the other hand, was followed by four months of intense suffering, so great, indeed, that he regretted not having objected to any measure which had been instrumental in drawing out his existence and thus extending his misery.

The progress of the above case is in marked contrast to that of a case of primary epithelioma of the larynx immediately below the vocal band, reported several years ago by the writer in the New York MEDICAL RECORD.

In this, the presence of a tumor so small and so completely concealed by the overhanging vocal band that it could not be detected by the laryngoscope, and in the earliest stages of its development, was sufficient to cause fatal dyspnœa.

1 EAST THIRTY-THIRD STREET.

NOTE ON THE DETECTION OF SUGAR IN URINE.

By GEORGE B. FOWLER, M.D.,

PROFESSOR OF CLINICAL CHEMISTRY IN THE NEW YORK POLYCLINIC, ETC.

In Dr. Satterthwaite's interesting *résumé* of the subject of glycosuria, in this journal of April 11th, there is one statement which is incorrect, and which on account of its practical importance should not be allowed to pass unnoticed. I allude to the sentence, "It may be as well at this point to note that Trommer's and Fehling's methods are thoroughly satisfactory in most cases where sugar is present, though on the whole the latter is less apt to be misinterpreted." The frequency with which I encounter this error has impressed me with the evident confusion which exists regarding the matter of testing for sugar in the urine. Now, Trommer's test for sugar depends upon the property which grape-sugar has of immediately reducing the oxides of copper in a boiling alkaline solution. The fact is, however, that *Trommer's test is not applicable to the urine*, except when applied under certain important conditions.

If any one will take the trouble to prepare a watery solution of honey, and to some of it in a test-tube add three or four drops of a solution of copper sulphate (gr. xxx. to ʒ j.), and then render the whole alkaline by sodic or potassic hydrate (gr. xxx. to ʒ j.), and boil, he will observe the following characteristic changes: When the copper sulphate is added the clear watery fluid simply assumes a greenish hue. When the alkaline solution is added there first appears a light-green precipitate (hydrated cupric oxide) which, on the addition of an excess of the alkali, subsequently clears up, giving place to a perfectly clear and beautiful blue solution. On boiling, the whole turns yellow, or orange, from the precipitation of the insoluble red oxide of copper.

Now make a solution of honey in urine and proceed to apply the test as before. All will go well until the last step; for, on boiling, the mixture simply loses its blue color, changes to a clear, amber-colored fluid, like the original urine, and shows no precipitate save that of the flocculent earthy phosphates thrown down by the boiling alkali; and the color will be darker than the urine on account of the action of the alkali on the sugar. Just compare the two results. These points have long been known, and yet most of our books persistently disregard them.

Certain ingredients of the urine, therefore, probably the coloring matter, interfere with the reaction of Trommer's test, and the custom formerly was, first to filter the suspected urine through animal charcoal, whereby it is deprived of all color, and will then react perfectly well. But this is rather troublesome. So that, with the view of ascertaining the nature of the interference, and, if possible, how easily to avoid it, I some years since directed my attention to the subject, and published a modification of Trommer's test, whereby it can be safely employed in urinary solutions of sugar (*New York Medical Journal*, June, 1874, p. 632), and, although several authors have incorporated it, I beg leave to briefly reiterate the chief points.

The red oxide of copper precipitated from a few drops of copper sulphate solution in a boiling alkaline solution of saccharine urine, is redissolved as fast as formed. But this only occurs when an excess of urine is used. If, on the other hand, we employ an excess of copper sulphate, the conditions will be such as to prevent any interference, and the reaction will be prompt and characteristic. My modification, then, consists in taking about five drops of the suspected urine, and to it adding two or three drops of a strong solution of copper sulphate (ʒ j. to ʒ j.). The alkali is carefully poured in until the clear blue color appears, when, on boiling, if sugar is present in appreciable amount, the red oxide of copper will be thrown down. If boiling changes the mixture to a dark transparent urine color, sufficient copper sulphate has not been used. If, on adding the alkali in excess, the pale-blue precipitate of hydrated cupric oxide does not disappear and give place to a clear blue solution, either too much copper sulphate has been employed, or sugar is not present. When either of the last two results are obtained, the experiment must be repeated with varying proportions of the reagents.

Fehling's liquor is a graduated solution of copper sulphate in liquor potassæ or sodæ, and is intended for volumetric analysis, although it is equally applicable for qualitative tests. Its clear blue color is due to the presence of some organic acid or salt—usually tartaric acid—and being already prepared, it is by far the most convenient and certain test for the physician's use. Taking about a drachm in a test-tube, boiling, and adding the urine drop by drop, the conditions are the same as in my modification of Trommer's. The only precaution necessary with it is always to boil before adding the fluid to be tested, because, on keeping for any length of time, the organic salt or acid which it contains itself reduces the copper sulphate in a manner similar to sugar.

A CASE OF HUMAN BITE FOLLOWED BY SEPTICÆMIA—RECOVERY.

By JAMES STRATTON CARPENTER, A.M., M.D.,

POTTSVILLE, PA.

It is only within a comparatively recent period that the attention of the medical world has been drawn to the possession by human saliva of a virulence, which, under certain conditions, is hardly surpassed by that possessed by the poison of the rattlesnake and others of its class. It was that celebrated investigator Pasteur, to whom we owe so much, who, no earlier than 1881, proclaimed his discovery of "a new disease," from injecting into the subcutaneous connective tissue of a rabbit the saliva obtained from a child that had died of hydrophobia, and the experiments of Dr. Sternberg, U.S.A., subsequently, who employed *normal* human saliva, have furnished sufficient evidence that, however harmless we have been accustomed to regard this secretion of the salivary and other glands, and as potent only for physiological functions, we must henceforth accord to it another and more dangerous quality that brings its study into the realm of pathological inquiry, and forces attention to it on account of the interest it possesses from a surgical point of view.

These experiments of Dr. Sternberg, which have been repeated for the most part by Dr. Claxton (vid. *Medical Times*, vol. xii., No. 380), have fully established the fact that when normal human saliva is injected into the subcutaneous connective tissue of rabbits, death ensues in from twenty-four hours to three weeks. When larger animals were experimented on only local symptoms, in the production of abscesses at the seat of puncture, were obtained. And we are accordingly led to the inference that the potency of the poison diminishes as the size of the animal experimented upon increases in the scale of being—an inference which is not supported by the results of the case here reported.

I have nothing to contribute in the way of experimentation upon this normal secretion of the human economy. All experiments, when entered upon with a view to emphasize the beliefs of the individual who conducts them, are apt to be viewed with distrust, and he is sure to meet with unfavorable comment at the outset if his deductions clash with long-accepted opinions. Particularly are experiments of this character liable to be frowned upon when they are scrutinized by the microscope of German methods, and viewed from the laboratory windows of an imitator of Koch and others of that school. Woe be to him if, in their opinion, at any point a loophole of entrance be discovered where that enemy to profitable medical discussion, the much-abused bacillus or micrococcus, may have crept in unawares!

But I simply desire to record a case which, in the light

of these recent investigations, seems to be possessed of especial interest, and is contributed by me with no other idea than the wish to place on record the results of an introduction into the human system of a small amount of human saliva placed there with no thought of experimentation whatever.

Case.—Owen M——, laborer, aged thirty-five years, while attempting to stop a domestic brawl was himself set upon by the intoxicated head of the household, and, in the scuffle which ensued, was bitten by his assailant on the front and back of the distal phalanx of the third finger of the right hand. The wound on the dorsal aspect of the finger was but a slight scratch in appearance and soon healed; but that anteriorly was of a punctured character, leaving the mark of a single tooth and bled quite freely so as to saturate the rag wrapped about it. The wound was cauterized by the physician first called in, who did not return subsequently, and for nearly four weeks the patient made use of various home remedies, poulticings, salves, etc., until becoming alarmed at the condition of his finger, he sent for me just one month after the infliction of the injury.

The appearance of the hand was as follows: There was great swelling of the third finger, with discoloration, it being three times its natural size, and of a dark purplish hue over its whole extent. The skin on the dorsal aspect of the finger was of a glistening character, due to the tension exerted upon it by infiltration into the tissues; while along its palmar aspect half-a-dozen openings were visible, leading down to the bone and discharging a very unhealthy-looking pus. There were numerous granulations along its whole extent, excepting at the proximal phalanx, which was not deprived of its dermal covering, but was the seat of a purulent collection and a fistulous tract, at the bottom of which dead bone could be detected. The hand was puffy in appearance, but no sign of anything more than œdema of the tissues would present. The patient's general condition was by no means good, and symptoms of hectic had been noticed the past few days. The pulse was rapid and feeble, over 100 per minute, and fever generally set in toward afternoon; sweatings were beginning to bother him; anorexia had existed for some days; there was obstinate constipation; the breath was offensive; the tongue heavily furred; and sleeplessness had began to tell its story in his face, which was pallid and sunken.

Under circumstances such as these I strongly advised immediate sacrifice of the finger, but was obstinately met by the members of the man's family as well as himself, who "did not want it taken off;" so I agreed, under protest, to see what several days' treatment would bring about, allowing them to assume the responsibility of the delay. I laid open the finger by a deep incision anteriorly, established free drainage in the wound, and used aseptic dressings, but all to no purpose, and amputation of the finger at the metacarpo-phalangeal articulation was done March 15th, the only results of the delay being, as I had feared, an increase in the constitutional disturbance before noted.

The subsequent history of the case was but what the constitutional condition of the patient had led me to expect, and only at this date, over five weeks subsequent to the performance of the amputation, has the wound healed and the convalescence of the patient been established. Septicæmia became more and more pronounced, and for some days the issue of the struggle was a very doubtful one. Œdema of the hand and arm occurred extending up to the elbow; on the index and middle fingers of the right hand, several days after removal of the third finger, could be seen several blebs containing a bloody serum, which in twenty-four hours' time had so extended that both fingers became suppurating sores, and, on being freely incised discharged an ichorous pus, and for nearly ten days were in this condition, which fortunately went no further. A dark-colored swelling appeared on the posterior aspect of the arm, just above the wrist, which I feared might be the precursor of a similar outbreak there to that noted in the two fingers, but it gradually disappeared without further trouble. Pain was felt from the hand up to the axilla, and there was at one time a slight enlargement of the axillary glands. The wound assumed a most unhealthy appearance; a whitish-gray deposit, diphtheritic in character, lined the bottom and sides of the incision, which was thickened and of a dusky-red color along its edges, the blush extending over a considerable portion of the dorsum of the hand. A slight discharge of unhealthy pus kept up for several weeks from the wound, and, as it showed no disposition to heal, all tension was removed, and granulation favored by use of carbolized and iodoform dressings in conjunction with the oxide of zinc ointment.

To keep pace with the local outburst the patient's constitutional symptoms became more alarming each day. There was great physical prostration, the febrile symptoms assumed those of a continued type, and the frequency of the pulse was increased to 130 to 140 per minute. There were colliquative sweats day and night, drenching the bedding and causing great exhaustion. But the absence of well-defined rigors—only chilliness being at any time complained of—the ability of the patient to take nourishment freely, and, in spite of the large doses of quinine and iron, the absence of any gastric irritability, these conditions led me to believe that the struggle would not be a hopeless one.

The treatment was tonic and supportive in character, the usual dose of quinine and iron at first employed being increased, subsequently to grs. xxiv. quiniæ sulph., and gtts. cxx. tr. ferri chlor., every twenty-four hours, which he took continuously for three weeks, the only effect subjectively on the patient of so much quinine being to cause a slight "singing" in his ears. Only one day, when I had ordered grs. xxx. of quinine to be given, was deafness produced, and the extra capsule was omitted afterward. Since April 18th he has been taking grs. xx. *per diem*, and the amount of iron has also been reduced to gtts. lxxx. daily.

To overcome the obstinate constipation, after a whole box of aperient powders had failed to move the bowels, I ordered:

℞. Ext. colocynth. c..... ʒ ss.
Ext. nucis vomicæ..... grs. iij.
Aloin..... grs. v.
M. ft. pil., no. xx. S.—One three times a day.

For the colliquative sweats I ordered a pill containing grs. iv. zinci oxidi, gr. one-fourth ext. bellad., and gr. one-third ext. nucis vomicæ, to be taken at bedtime, and repeated during the night if necessary. This greatly, though not entirely, relieved the patient, and I latterly prescribed a pill containing grs. iij. acidi gallici and gr. one-fourth ext. bellad., two of these being taken at bedtime, and with good effect. Singularly enough, what perspirations he now has are entirely limited to the right arm.

Brandy was freely given in the form of egg-nogg, which proved a very acceptable drink to the patient; nearly two quarts of milk were consumed daily, with broths and soups in addition; yet only at present writing, April 19th, five weeks after the amputation of the finger, and nine weeks subsequent to the date of the original injury, has convalescence been secured.

Comparing the results obtained by experiment on the lower animals, and those which are furnished by the study of this case of human bite, what do we observe?

1. As to the nature of the disease produced by saliva. It is unquestionably septicæmia, which, though not fatal in the case reported, as with lower animals experimented on, was of so serious a character that recovery was by no means an assured thing until many weeks of danger had passed by.

2. *The pathological appearances*, which experiment determined to "consist of a diffuse inflammatory œdema

or cellulitis situated about and extending from the seat of inoculation," in the case here reported, will be seen to conform exactly, so far as it goes, to the description above quoted.

3. What constitutes the difference in the virulence of the saliva of different individuals? The theory that nicotine destroys the septic micrococcus, affirmed to be the constituent of saliva capable of producing disease, may experimentally be true; but in the case reported the man's assailant was an inveterate user of tobacco, which did not, apparently, influence the results in the case in the direction named.

4. What factor in human saliva is it that produces the results described? Dr. Sternberg defines it as "a micrococcus which multiplies in the subcutaneous connective tissue, and also in the blood, shortly before or after death." And the progress of symptoms in the case seem to bear out this statement, as there was a period of incubation preceding the invasion of the disease, occupied by the micrococcus in multiplying itself, followed by the production of "the diffuse inflammatory cellulitis situated about the seat of inoculation and extending from it," and finally producing systemic infection, which was so nearly fatal to the patient.

Progress of Medical Science.

The Thermo-Cautery in Enlargement of the Thyroid Body.—The method of Dr. Weiss consists in touching the skin over the tumor with a small Paquelin's cautery, held like a pen. Touches with this instrument are made in horizontal rows, the rows being about one centimetre apart, and the touches in each row being close together. If the cautery be at a white heat, the procedure causes very little pain. Anæsthesia, general or local, is quite superfluous, and so is all after-treatment, but a little cotton-wool may be laid upon the site to prevent friction by the clothes. A thin dry scab falls from each spot after about six days. After seven or eight days the procedure may be repeated, and so on for six, eight, or a dozen times, according to the extent of the original enlargement. It is most valuable in the purely hypertrophic variety, but in the cystic also is of great advantage if the cysts be punctured with a Pravaz's syringe. In obstinate cases, the above method is rendered somewhat more severe by applying vaseline directly after the use of the cautery. The effect is to cause the premature separation of the small scabs, which is followed by a slight suppuration for a few days. The explanation of the good effects of Paquelin's cautery, so applied, is presumably this: Weiss believes that the irritation brought to bear on the nerve-endings in the skin causes constriction, more or less persistent, of the arterial muscular coats, which induces defective nutrition of the hypertrophic gland-substance, and its gradual disappearance.—*Berliner klinische Wochenschrift*, No. 2, 1885.

The Varieties of Gastric Disease.—Riegel believes that the stomach must always be washed out in accordance with Leube's plan before an accurate diagnosis can be made. A healthy stomach has perfectly finished the digestion of an ordinary meal in seven hours, and Riegel confirms this. But, conversely, the fact that the stomach is empty after such period does not necessarily prove the absence of disease, as both in gastric ulcer and in Leube's "nervous dyspepsia," digestion is not delayed. In most gastric diseases, however, there is delay, and the next question is—its cause. To this end, the gastric juice must be examined. Riegel rejects Leube's method of cold-water injection, and endeavored to procure the contents of the stomach as undiluted as possible; these he afterward examined for acids and pepsine. The best reagent for free hydrochloric acid was found to be methyl-anilin-violet, and for the separation of lactic and butyric acids from the former, Uffelman's test of carbolate and chloride of iron (*Archiv für klin. Med.*). The amount of pepsine was estimated from the time required for the complete digestion of a very small quantity of albumen. As a result, cases of gastric diseases are divided into three groups. 1. Cases characterized by the absence of free hydrochloric acid, and the presence of lactic and butyric acids; pepsine being almost or entirely absent. This condition was found mainly in cancer, and in dilatation from cancerous constriction of the pylorus. The hydrochloric acid is regarded as normally secreted, but it is destroyed by the cancer, according to Professor Riegel. 2. Cases presenting a sour fermenting liquid, containing much lactic and butyric acid, also free hydrochloric acid; the digestion test indicating a fairly normal amount of pepsine. To this category belong the cases of gastric disorder from fermentation, well described by Naunyn. Methodical washing out is of the greatest value in these cases. 3. Cases in which the digestion is considerably prolonged; hydrochloric acid is abundantly present, organic acids are absent or nearly so, and the digesting power of the gastric juice is normal. It is shown that the further addition of hydrochloric acid does not quicken, but rather hinders digestion. An excess of organic acids, with excess of hydrochloric acid, hinders digestion, and acid fermentation is induced. Practically speaking, hydrochloric acid should only be given when there is a deficiency of acid in the gastric contents during digestion, as shown on examination.—*Archiv für klinische Medizin.*

Observations on the Cutaneous and Deep Reflexes.—Dr. P. C. Knapp, of Boston, records, in the April number of *The American Journal of the Medical Sciences*, a series of observations, upon the cutaneous and deep reflexes of 239 persons, from which he draws the following conclusions: 1. Absence of the plantar or cremaster reflex is usually pathological, depending upon a direct lesion of the reflex arc, or some cerebral disturbance. 2. Absence of the other cutaneous reflexes is not necessarily pathological. 3. Absence of the patellar reflex may be due to cerebral disturbance, especially in alcoholic subjects. 4. Ankle and patellar clonus are pathological. 5. The deep reflexes of the upper extremity are of frequent occurrence, and have no special pathological significance. 6. The costal reflex is found in the majority of cases without general exaggeration of the reflexes, and with no signs of phthisis, incipient or advanced. 7. When the reflexes differ on the two sides, though it usually signifies some unilateral disease of the nervous system, it is not always pathological. Finally his observations have led him to emphasize the value of testing all the reflexes, cutaneous and deep, in the upper extremity as well as in the lower, and on the two sides of the body, in examining patients with nervous diseases.

A Contribution to the Pathology of Malarial Fever.—Drs. W. T. Councilman and A. C. Abbott, of Baltimore, report, in the April number of *The American Journal of the Medical Sciences*, two cases of malarial coma, with post-mortem examination, of especial interest in connection with which was the presence of small hyaline masses in the brain and elsewhere. The authors fully consider the arguments pertaining to the supposition that these hyaline bodies are living organisms, without being able to arrive at any definite conclusion. With a view of shedding some light on the subject of lower organisms in malaria, they made a careful search for the bacilli of Klebs and Tomasi-Crudeli, and for any other lower organisms in all of the cases of malarial fever which came under their observation on the post-mortem table. In no case were any bacilli, bacteria, or micrococci found. Only in the two comatose cases, which they have fully derscribed, were the singular hyaline bodies found. This is an argument against the probability of these hyaline bodies being micro-organisms. They cannot suppose the comatose form of malarial poisoning to be a special disease, and were a lower organism found in this, it should also be found in other cases.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 2, 1885.

THE AMERICAN MEDICAL ASSOCIATION.

THE meeting of the American Medical Association, held during the past week in New Orleans, as will be seen by our telegraphic reports, was a fairly successful one. The attendance was good, and much interest was manifested in the work of the general sessions as well as in the papers read before the principal sections. The subjects selected were for the most part of practical interest and elicited considerable discussion.

The work of the council was well done in disposing of many of the vexed questions which are liable to be ventilated in open session, thus saving much time and avoiding undignified and angry debate. It was, however, apparently necessary to understand the inward workings of the Committee on Organization of the International Medical Congress, as much dissatisfaction has been shown in different parts of the country regarding the appointments made. In some respects there was reason for this.

The discussion which was seemingly necessary to get at the points in dispute, ventilated a great deal of the intolerant spirit against the New-Code advocates, which every fair-minded and peace-loving medical man will be sorry to note. The American Medical Association is in some respects a representative body, but it can hardly arrogate to itself the right to control absolutely the still more widely representative character of the International Medical Congress, at least so far as the election of the entire membership to the latter body is concerned. It is a matter for congratulation that, after calling the committee to account for transcending its authority, the whole matter was amicably and impartially settled. The election of Dr. William Brodie, of Detroit, to the presidential chair was a fitting compliment to the man and a retroactive honor to the Association.

TO ABOLISH VACCINATION.

PROBABLY few things could more decidedly advance the material interests of practising physicians than the abolition of vaccination, and the rehabilitation of small-pox among us. Only on the ground of humanity and right do we continue to plead for the universal use of Jenner's discovery, despite the constant assaults with opprobrious epithets by a small but ever-sizzling section of hebetudinous crankdom.

Recently Mr. Alfred R. Wallace, LL.D., a gentleman of scientific reputation in some directions, has furnished us with another array of statistics showing, as he believes the utter inutility and even positive danger of vaccination. These statistics are taken from the Registrar-General's returns, and show the number of deaths per million in London, and in England and Wales, yearly, from 1838 to 1882. A diagrammatic table is given by which it is seen that the average diminution of small-pox mortality from the first to the second half of the period (1838–1882) is fifty-seven deaths per million (in London), while that from typhus and typhoid fevers is three hundred and eighty-two per million, or six times as much as that from small-pox. The fact, however, that the other zymotic diseases, taken as a whole, in London, have not diminished proportionally so much as has small-pox, is passed over by the distinguished and ingenuous author. The lines of his diagrams appear also to go directly against the lines of his reasoning, when applied to the relative decrease in small-pox and the other zymotic diseases in England and Wales.

Professor Wallace marshals other figures in order to prove that vaccination does not mitigate the severity of the attack of small-pox. And his selected figures do show that before vaccination the average mortality was 18.8 per cent., now it is 18.5 per cent.

An elaborate analysis of the small-pox death-rate in the army and navy is given. In these services vaccination is rigidly enforced, but the result is that there is still an average annual mortality of .0083 per cent. (!) in the army and .0157 per cent. in the navy, which it is claimed is only a little better than the rates in the civil adult population (.0176 per cent.).

Professor Wallace puts forward a large number of other figures to prove a large number of other points. The more these figures and the accompanying explanations are examined, however, the more apparent is it that whatever Mr. Wallace is as a naturalist, he is both shallow and silly on the subject of vaccination. Apart from the fact that he does not dare to compare pre-vaccination and post-vaccination periods, or use the statistics of other countries, the unbiassed study of the very diagrams which he parades disprove the points he would make.

THE GEOGRAPHICAL DISTRIBUTION AND THE DIAGNOSIS OF IDIOPATHIC ANÆMIA.

DR. J. H. MUSSER, of Philadelphia, has reported certain cases of idiopathic pernicious anæmia, and has collected, in tabulated form, all the cases so far recorded in this country. Of these cases, thirty-nine in number, fifteen were observed in Philadelphia, thirteen in Canada, eight in Boston, and the remaining three in separate localities. The perniciously anæmic centres in this country, therefore, are apparently the three places above mentioned. Dr. Musser, however, disclaims any endemic inference, and ascribes the peculiar distribution to the fact that clinical observation has been more awakened toward this disease in the localities named. Another possible explanation, however, is that this same observation has been more critical in some of the non-anæmic centres, and has refused to accept the diagnosis of idiopathic anæmia so readily as is sometimes done. Excluding nine cases in which lesions of the bone marrow were found on autopsy, there are remaining thirty cases in Dr. Musser's table. Of these, five are reported cured, or about six-

teen per cent., and five improved. Of those that died, there were no autopsies held in nine cases. It appears then, that in one-third of this thirty the anæmia was not progressively pernicious, and that in another third (nine cases), organic disease cannot be excluded. In five cases, also, evidence of emaciation is noted, a symptom supposed not to characterize the idiopathic form of the disease.

The diagnosis in two-thirds of the cases, therefore, must have been based upon the clinical history alone. It has yet to be decided that such kind of evidence is sufficient, if we exclude the most characteristic feature of the disease, viz., its progressiveness. Dr. Musser, however, modifies the definition of idiopathic anæmia, giving it sufficient elasticity to include the thirty-nine. The disease is, he says, only "generally progressive," and "too often pernicious," while, in addition, it is characterized by diminution in number and change in the appearance of the red blood-cells, by retinal and other hemorrhages, by occasional fever, and by the absence of emaciation.

There is as yet no pathognomonic sign of idiopathic anæmia, provisionally so called. A case cannot be positively diagnosticated until it has passed through a most careful ante-mortem and post-mortem examination. At the same time we can quite readily admit that there is an anæmia having more or less of a clinical individuality, which physicians can sometimes recognize as probably distinct from simple or symptomatic anæmia. If such a case ends fatally, and autopsy reveals no cause of the symptoms, the diagnosis of idiopathic anæmia is confirmed, but as yet it is only by such an untoward *finale* that the clinician's conclusions can be affirmed.

News of the Week.

Death in the Dentist's Chair.—The daily papers give an account of a young woman of Chicago, who died under the influence of chloroform while in a dentist's chair, April 27th. The dentist, Dr. N. W. Day, administered chloroform at the lady's own request.

Death of a Medical Centenarian.—Dr. Oliver Swaim Taylor, of Auburn, N. Y., doctor and clergyman, died recently at the age of one hundred years. He was born in New Ipswich, N. H., December 17, 1784. He graduated from Dartmouth College in 1809, and graduated in medicine in 1813. Finding teaching more congenial than the practice of his profession, he gave little attention to medicine, but taught many men who have since become famous.

Dr. Barber's Article on "Alcoholic Hyperæsthesia."—The article on the above subject was incorrectly attributed to Dr. Barker, instead of to Dr. C. F. Barber, of Fort Hamilton.

Erratum.—Dr. Hamilton, whose article appeared in The Record of April 4th, requests us to make the following corrections: Francke H. Bosworth, instead of J. H. Browne (p. 365), Exner instead of Lyner (p. 365) and Ixner (p. 366); *succedaneum* instead of *succideum* (p. 368).

Protesting against Color-test Examinations.—The Delaware & Hudson Canal Company have adopted the plan of requiring employees to submit to color-test examinations as well as to tests of visual activity and hearing. It is stated that the Brotherhood of Locomotive Engineers have resolved not to submit to such a test. The men are willing to undergo any examination when the code of signals, etc., in use on the road is used, but claim that it is unjust to ask them to submit to an examination where colored yarns instead of lights are used. The company's regulation says: "Imperfections of sight or hearing or inability to nicely distinguish shades of color shall not be regarded as sufficient grounds for removal. Only absolute inability to distinguish red or green, nearsightedness, or deafness shall incapacitate an employee and be regarded sufficient cause for removal." The company's requirement is only just, and is in the interests of its passengers.

The First Cremation in England.—On April 6th the crematory which was erected at St. John's, Woking, Surrey, was made use of for the first time for a human cremation, and the body reduced to ashes was that of Mrs. Pickersgill, of London. It had previously been subjected to an autopsy. The deceased lady was well known in literary and scientific circles, and expressly stipulated in her will that her body should be cremated after death.

An Epidemic of Typhoid or Malarial Fever.—Plymouth, Penn., a town of about 8,000 inhabitants, has been suffering from a severe epidemic of typhoid and malarial fevers. Some seven or eight hundred persons have been taken ill, and from five to twelve deaths a day are reported. The cause is said to be the absence of proper drainage. Refuse matter has been allowed to accumulate around the houses or was put into cesspools. These cesspools were never emptied, but when one was full another was dug beside it. This soil, saturated with filth, was pierced by the shallow wells from which the inhabitants take the water which they drink and use in cooking. As there had been at last reports (April 28th) only twenty-five deaths, it is evident that the most of the cases are not typhoid.

The Bridgeport (Conn.) Hospital has just received the sum of $5,000 from the estate of the late Mr. Frederic Marquand.

The Cholera Bacillus War.—At a meeting of the Münich Medical Society, April 1st, another notable discussion upon the cholera bacillus took place. Professor von Pettenkofer renewed the expression of his well-known "localist" views. Dr. Emmerich came forward with fresh arguments and experiments to prove that his "Naples-bacterium," and not Koch's bacillus, is the true cause of cholera. Emmerich claimed to have successfully inoculated thirty guinea-pigs, four dogs, six cats, and one monkey. Emmerich's bacterium is found, as he claims, not only in the intestines, but in the blood and tissues. We learn from the *Berliner Klinische Wochenschrift* that Koch will take the opportunity soon at a coming cholera conference, to disprove "in a striking manner" the views of the Münich school.

Professor Leyden is to succeed the late Professor Frerichs in the Berlin University Medical Faculty.

THE COLLEGE OF PHYSICIANS of Philadelphia, says the Boston *Medical and Surgical Journal*, has finally secured sufficient funds to place a third story upon the well-known structure at Thirteenth and Locust Streets. The work will begin next month. The improvements are estimated to cost nearly thirty thousand dollars, most of which was subscribed by Fellows of the College.

ORGANIZATION OF A MEDICAL SERVICE FOR THE RIEL REBELLION.—A staff of medical officers has been appointed for the purpose of organizing a medical service in the half-breed rebellion.

Reports of Societies.

American Medical Association.

Thirty-sixth Annual Session, held at New Orleans, La., April 28, 29, and 30, and May 1, 1885.

(By Telegraph to THE MEDICAL RECORD.)

TUESDAY, APRIL 28TH—FIRST DAY.

THE Association met this morning, and was called to order at eleven o'clock by DR. SAMUEL LOGAN, of New Orleans, Chairman of the Committee of Arrangements.

A prayer was offered by the Rev. B. M. Palmer, D.D.

DR. LOGAN then introduced the President, Dr. Henry F. Campbell, of Augusta, Ga., and afterward delivered

THE ADDRESS OF WELCOME,

which was timely and well received.

THE PRESIDENT invited the ex-Presidents to take seats on the platform, and Drs. T. G. Richardson, of New Orleans, N. S. Davis, of Chicago, and J. M. Toner, of Washington, responded.

DR. CAMPBELL then delivered the

ANNUAL ADDRESS OF THE PRESIDENT,

in which he made a graceful recognition of the honor conferred upon not only himself, but the great Southern State he represented. He eulogized the long list of illustrious men who had guided the deliberations of this national body, from the noble Chapman to the beloved Flint, and made special reference to Drs. Gross and Sims, expressing the hope that the contemplation of the present and our dreams of the future might be as bright as the golden history of the past. He then paid glowing compliment to those living who had labored zealously, and were mighty and invulnerable in the promulgation of the truth, and with a soul-stirring tribute of respect to the father of the Association for his watchfulness over its interests, his tenacity for its honor, and increasing labor for its advancement, he closed his sketch of the past and the present illustrated with pictures of dead and living men.

The President then spoke of New Orleans and the International Exposition, and compared them with the American Medical Association and the International Medical Congress, all of which were representative bodies with broad constituencies.

From his predecessors had emanated suggestions which had been formulated and had become fundamental parts of this national scientific body, and notable instances were the assured and satisfactory success of the *Journal of the Association*, and the organization of the Ninth International Medical Congress.

He asked early and systematic attention to the problem of forensic medicine, including the medical witness, the medical expert, and the medical defender, and suggested that a new section be formed to which all discussions, papers, and reports concerning

THE RELATIONS OF MEDICAL MEN TO TRIBUNALS OF LAW

could be referred.

On motion of DR. BRODIE, of Detroit, a vote of thanks was tendered to the President, and the address was referred to the Committee on Publication.

On motion by DR. QUINBY, of Jersey City, it was agreed that that part of the President's address relating to forensic medicine be referred to a committee of five, to be appointed by the Chair, and to report within the present meeting.

The report of the Special Committee, Dr. Austin Flint, Sr., of New York, Chairman, on

THE DEATH OF SAMUEL D. GROSS,

was read by DR. T. G. RICHARDSON, of New Orleans, and referred to the Committee on Publication.

DR. JOHN BILLINGS, U.S.A., in the absence of Austin Flint, Sr., reported the success of the Special Committee in securing an appropriation from Congress for the erection of a

FIRE-PROOF BUILDING FOR THE ARMY MEDICAL MUSEUM AND LIBRARY AT WASHINGTON,

and, in behalf of the Medical Department of the Army, returned thanks to the Association for the tokens of confidence and approval manifested in the institutions represented by the Library and Museum. The report was accepted, and referred to the Committee on Publication.

Dr. Billings reported the action which had been taken concerning the next International Medical Congress by the Executive Committee, in conformity with resolutions adopted at the last annual meeting of the Association, which has received publication in the medical journals throughout the United States.

On motion of DR. KELLER, of Arkansas, the report was made the special order for Wednesday at 12 noon.

The report of Dr. A. L. Gihon, on the subject of the

ERECTION OF THE MONUMENT TO DR. BENJAMIN RUSH

was presented, and on motion by DR. TONER, of Washington, made the special order for Friday morning.

SEVERAL PAPERS WERE READ BY TITLE

and referred to the Chairman of the Section on Surgery, having been received too late to enter the printed programme.

The following gentlemen were made

INVITED GUESTS:

Drs. Edward Jones, A. B. Miles, and C. J. Bickham, of New Orleans; A. E. Forte, of Philadelphia; J. J. Gauthereaux, of St. James, La.; and James R. Scarborough, of Clinton, Ky.

A communication from the Medical Association of South Carolina on

THE DISCOVERY OF THE ANÆSTHETIC PROPERTIES OF SULPHURIC ETHER

was presented by Dr. R. A. Kinloch, of Charleston, and on motion by DR. BEVERLEY COLE, of San Francisco, was referred to the Section on Practice of Medicine and Materia Medica, with the request that it consider the subject and report to the Association.

The Association then adjourned, to meet on Wednesday morning at ten o'clock.

WEDNESDAY, APRIL 29TH—SECOND DAY.

The Association was called to order at 10 A.M. by the PRESIDENT and prayer was offered by the REV. J. K. GUTHEIM, D.D.

DR. LOGAN, Chairman of the Committee of Arrangements, announced the reception of a telegram from W. O. Baldwin, of Montgomery, Ala., regretting his inability to be in attendance.

The Secretary announced the following

COMMITTEE ON NOMINATIONS:

John Cochrane, Alabama; R. A. Kinloch, South Carolina; L. P. Gibson, Arkansas; R. B. Cole, California; H. O. Walker, Michigan; C. C. Wyckoff, New York; William Pierson, New Jersey; W. H. Phillips, Ohio; R. S. Sutton, Pennsylvania; D. W. Krouse, Iowa; J. A. White, Virginia; J. H. Murphy, Minnesota; N. T. Nelson, Illinois; T. G. Richardson, Louisiana; C. H. Shackford, Massachusetts; Job W. Smith, Florida; J. B. Robertson, Texas; S. S. Riddel, Wisconsin; E. F. Upham, Vermont; A. Y. P. Garnett, District of Columbia; L. D. Waterman, Indiana; G. W. Baldwin, Kansas; B. F. Coleman, Kentucky; S. C. Gordon, Maine; R. J. Nunn, Georgia; J. McAchran, Wyoming: Joseph R. Smith, U. S. Army; George Peck, U. S. Navy; John Godfrey, U. S. Marine Hospital Service; D. T. Nelson, Illinois; John S. Lynch, Maryland; G. M. Taylor, Mississippi; Le Grand Atwood, Missouri; R. C. Moore, Nebraska; W. E. Anthony, Rhode Island; D. J. Roberts, Tennessee; J. H. Pipes, West Virginia; C. J. O'Hagan, North Carolina.

The next order of business was

THE ADDRESS OF THE CHAIRMAN OF THE SECTION IN PRACTICAL MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY,

by DR. H. D. DIDAMA, of Syracuse, N. Y., who said that a literal compliance with the requirement of the by-laws, that a summary of the progress made in these departments during the past year, would subject the Association to a wearisome recital of facts which had already been gathered and widely scattered again through the medium of medical journals. Special attention was directed to only two topics which had most recently engaged the observation of the profession, namely

THE COMMA BACILLUS

and the hydrochlorate of cocaine. The speaker then reviewed the present aspect of the question of the relation which cholera and the comma bacillus sustain to each other, and then referred somewhat extensively to the general subject of bacteriology and to the little help which it had given to the art of healing. But this negative result, so far as treatment was concerned, did not detract in the least from the value of the discoveries and the spirit of inquiry should not suffer thereby. Let us labor and wait and in the meantime direct a little more attention toward prophylaxis and therapeutics. Dr. Didama then reviewed the views of the neurologists who claim that a large proportion of diseases have their origin in disturbance of the nervous centres and regard fever, rheumatism, etc., as neuroses. He alluded to humoral pathology, in which derangements of the blood were essential factors in etiology, and to the solidists who pin their faith to cellular pathology. Neither view was absolutely true and neither wholly false. Each might be a factor in the origin of disease and each the last in the circle of etiological causes. The chairman closed his address with a study of the reparative power when disease has invaded and of the resisting power to the invasion.

On motion the address was referred to the Committee on Publication.

THE ADDRESS OF THE CHAIRMAN OF THE SECTION IN OBSTETRICS AND DISEASES OF WOMEN

was delivered by DR. R. S. SUTTON, of Pittsburgh, Pa. The subject of the address was

ON OVARIOTOMY.

The first part of it was devoted to the history of the conditions surrounding McDowell's first case. The deviations from McDowell's method of performing the operation were then carefully traced up to the present day, and the conclusion reached was, that the operation, as left by McDowell, was almost as complete as at the present time. Two essential improvements were the introduction of the cautery by Baker Brown, and the cutting off of the long ends of the ligature by Nathan R. Smith. Dr. Sutton then showed that from McDowell's operation nearly all the intra-abdominal operations in surgery had sprung, and noted carefully the lectures and papers delivered on the subject during the last twelve months. He insisted, as in all former papers, upon greater care in the surroundings of all intra-abdominal operations, and in further proof of his position, pointed to the admirable results obtained by John Homans, of Boston, and Robert Battey, of Rome, Ga., both of whom used the carbolic spray. He stated that for himself he did not use the spray, but looked upon cleanliness and Listerism as linked so closely together that they might be said to be inseparable, for

LISTERISM IS THE GOSPEL OF CLEANLINESS.

Mr. Lawson Tait had said to him: "I have sold all my right, title, and interest in Listerism with my tea-kettle to Battey." At the close of his address, Dr. Sutton referred to Dr. J. Marion Sims as one whose name was synonymous with the surgery of women, beloved of his own countrymen and honored by the entire surgical world.

On motion by DR. W. W. POTTER, of Buffalo, N. Y., the thanks of the Association were tendered to Dr. Sutton for his address, and the address was referred to the Committee on Publication.

DR. W. C. VAN BIEBER, of Baltimore, then delivered an address containing suggestions in regard to

THE CONSTRUCTION OF A HEALTH CITY IN FLORIDA, OR PENINSULAR AND SUB-PENINSULAR AIR AND CLIMATE,

and urged that change of air sometimes permanently arrests pulmonary disease in its first stage, and that the most favorable climate for yielding such a result was one where the temperature ranged from between 70° and 80° F., provided it is good, healthy air. Such a climate can be obtained on the Gulf Coast of the Peninsula of Florida, and if medical, social, and scientific interests would unite at once in the erection of a health city in the locality, it could be made so as to have no equal elsewhere.

The hour for the special order having arrived, the reading of Dr. Van Bibber's paper was discontinued.

DR. SHOEMAKER, of Philadelphia, then took the floor, and protested

AGAINST THE REPORT OF THE COMMITTEE ON THE INTERNATIONAL MEDICAL CONGRESS,

on the ground that the Committee had exceeded its authority; that it had yielded to the threat made by the New Code men at Copenhagen, that unless they were recognized they would use their influence to prevent the Congress from coming to the United States; that a bargain was made and that men from his own city who had declared the Medical Association to be

A "LOG-ROLLING, WIRE-PULLING ORGANIZATION"

had been lifted to exalted positions in the proposed official list of the next Congress.

DR. F. E. DANIEL, of Texas, offered the following preamble and resolution:

Whereas, At the last meeting of the American Medical Association a committee of seven was appointed to confer with the International Medical Congress, to be held in Copenhagen, with the view to securing the next meeting of that body in 1887, in Washington, D. C., and for the purpose of arranging for said meeting, and

Whereas, That Committee, after having accomplished said object, have proceeded, without authority from this body, to appoint the several officers of sections and

committees, which appointments have been published and thus acquired the color and aspect of an official action of this body, and

Whereas, This Association recognizes said Committee as a Committee of Arrangement only, it declines to recognize or accept the said appointments which it has made. Therefore be it

Resolved, That the Committee on Nominations be instructed to select and present to this body nominees for the office of president and all the other officers of the approaching International Medical Congress.

Dr. J. S. Billings, of Washington, said that all which had been said concerning a threat or a bargain at Copenhagen between the Committee and the New Code men was totally and absolutely untrue, that the Committee had enlarged itself and had performed the work it had done fully believing that it was in conformity with the resolution passed at the last meeting of the American Medical Association, which gave the Executive Committee full power in case the invitation was accepted to fix the time and to make all special and necessary arrangements for the meeting of the Congress, solicit funds, etc. The Committee as enlarged and as originally constituted was composed of men whose honesty of purpose and motives could not, with propriety, be questioned, and if any mistake had been made or any authority had been overreached, as there might be room for honest difference of opinion concerning the exact power of the Committee, it had been unintentional, and did not deserve an unqualified condemnation.

Speaking as a member of the American Medical Association he thought it unwise to condemn absolutely the work which had already been performed by the Committee, thereby suggesting that the work of organizing the International Medical Congress could be done by the Committee on Nominations in a single afternoon or at a single meeting.

Dr. Gabriel, of Ohio, was a delegate to Copenhagen, was consulted while there, and thought that the delegates should not have been ignored by the Committee.

Dr. Quinby, of New Jersey, thought that the Committee had entirely overstepped its authority, not intentionally, only in head and in heart.

Dr. Keller, of Arkansas, regarded the Committee as a creation of this Association, to which it should report as successive steps are taken. He offered the following as a substitute for Dr. Daniel's resolution:

Resolved, That the Committee appointed by the American Medical Association to arrange for the meeting of the International Medical Congress in 1887 be enlarged by the addition of members from this Association, one from each State and Territory, and from the Army and Navy, and Marine Hospital Service, and the District of Columbia, to be appointed by the present presiding officer, Dr. J. S. Lynch, of Baltimore, First Vice-President, and that this Committee thus enlarged shall proceed to review, alter, and amend the action of the present Committee as they may deem best.

Dr. Keller spoke against placing men in official positions in the organization of the Congress who were in direct opposition to the American Medical Association.

Dr. Cole, of California, said that while the Committee had erred, he would not accuse them of having done so deliberately in violation of their judgment. The fact that they had been reverenced had made them arrogant. He would simply have the enlarged Committee, if Dr. Keller's substitute should be adopted, cull the appointments, purify them, and place none in official positions who were not recognized as loyal to the Code of Ethics under which this Association was bound.

Dr. King, of Missouri, believed that while no one should doubt the honesty of the Committee, the conclusion could not be avoided that it had exceeded its authority. From the work which it had done it would seem that there was no West, no South, and only North and East. Besides, the Committee had gone outside and appointed gentlemen who are not members of this Association. He concluded by saying:

THE SPECIALISTS OF THE NEW CODE PERSUASION SHOULD BE TAKEN BY THE TOP OF THE HEAD AND THEIR THROATS CUT AT ONCE.

Dr. Shoemaker repeated that the delegates from this Association to the International Medical Congress were ignored by the Committee at Copenhagen, that the New Code men demanded a representation, that they had received recognition, and that they had been ignored.

Dr. Daniel thought that it was not right that the empire of Texas should be ignored as it had.

Dr. Sanders, of Tennessee, said that the Committee had placed its construction upon the instructions given by the Association, and that the proposition now was to almost absolutely ignore their honest efforts and adopt a resolution which would emasculate the entire work.

He offered as a substitute for Dr. Keller's substitute a resolution that the Association approves of the action of the Committee so far as it has been done,

PROVIDED THAT THE NAMES OF NEW CODE MEN ARE LEFT OUT.

Dr. Roberts, of Philadelphia, thought if the Committee had exceeded its power, it had been through error, that it was not the duty of the Committee to consult the delegates at Copenhagen, and that dissensions and a new order of publication at this state of the arrangements would seriously jeopardize the success of the next Congress.

Dr. Ghent, of Texas, said that it looked as though there was

"A BUG IN THE SHIP SOMEWHERE."

He favored Dr. Keller's resolution.

A MOTION TO ADJOURN WAS LOST

—ayes 44, nays 360, and a vote was called for on Dr. Sanders' resolution.

Dr. Toner, of Washington, suggested that a contingency should not be entertained. A division was taken, and resulted—ayes 88, nays 129.

Dr. Keller's resolution being in order, Dr. D. E. Bird, of Arkansas, offered an amendment that the States here represented collect through their representatives the additional members of the Committee, and the present presiding officer

APPOINT FOR THOSE STATES AND BODIES NOT REPRESENTED.

Dr. Keller accepted the amendment and, thus amended, his substitute for Dr. Daniels' resolution was adopted without dissent.

The Association adjourned to meet on Thursday at 10 A.M.

Thursday, April 30th—Third Day.

Association called to order by The President.

Prayer was offered by the Rev. W. H. Waters, D.D.

Dr. W. W. Potter, of Buffalo, N. Y., called up an

AMENDMENT TO THE BY-LAWS

offered last year by Dr. Foster Pratt, of Michigan, empowering each section to elect its own officers, on which discussion took place, and was followed by a motion that it be laid over for consideration next year, which was carried.

Dr. N. S. Davis, from the Standing Committee on

METEOROLOGICAL CONDITIONS AND THEIR RELATION TO PREVALENCE OF DISEASES,

reported and incorporated within the Report that of Professor K. H. Long, of the Northwestern University.

The report was accepted and the Committee continued.

Dr. Davis further reported concerning the subject of the

COLLECTIVE INVESTIGATION OF DISEASE

in co-operation with the Committee of the British Medical Association and the Committee of the International Medical Congress. The work has now so extended that a large number of nations have undertaken to perform it regularly, and the Committee recommended that work be extended to and performed, as far as possible, by State Medical Societies, and the details of investigation be carried out by means of cards obtained of the Central Committee.

The Report was adopted and referred for publication.

Dr. N. S. Davis, Chairman of the Committee appointed last year to make some

DECLARATIVE INTERPRETATION OF CERTAIN POINTS IN THE CODE OF ETHICS,

submitted the following report in the form of a preamble and resolutions :

Whereas, Persistent misrepresentations have been and still are being made concerning certain provisions of the Code of Ethics of this Association, by which many in the community, some in the ranks of the profession, are led to believe its provisions exclude persons from professional recognition simply because of difference of opinion or doctrine ; therefore be it

Resolved, That Clause 1, Article IV., in the National Code of Medical Ethics, is not to be interpreted as excluding from professional fellowship, on the ground of difference in doctrine or belief, those who in other respects are entitled to be members of the regular medical profession, neither is there any other article or clause in said Code of Ethics that interferes with the exercise of the most perfect liberality of individual opinion and practice.

Resolved, That it constitutes a voluntary disconnection or withdrawal from the medical profession proper to assume a name indicating to the public a sectarian and exclusive system of practice, or to belong to an association or party antagonistic to the general medical profession.

Resolved, That there is no provision in the National Code of Medical Ethics in any wise inconsistent with the broadest dictates of humanity, and that the article of the Code which relates to consultations cannot be correctly interpreted as interdicting, under any circumstances, the rendering of professional services whenever there is pressing or immediate need of them ; on the contrary, to promptly meet the emergencies occasioned by disease or accident, and to give the helping hand of assistance without unnecessary delay is a duty fully enjoined on every member of the profession, both by the letter and spirit of the entire Code, but no such emergencies or circumstances can make it necessary or proper to enter into professional consultation with those who have voluntarily disconnected themselves from the regular medical profession in the manner indicated by the preceding resolution.

(Signed) N. S. Davis, Chicago.
A. Y. P. Garnett, Washington.
H. F. Campbell, Augusta, Ga.
Austin Flint, Sr., New York.
J. B. Murdoch, Pittsburgh.

This report was adopted unanimously as an interpretation of certain clauses in the Code.

THE ADDRESS OF THE CHAIRMAN OF THE SECTION ON SURGERY AND ANATOMY

was then delivered by Dr. Duncan Eve, of Nashville, Tenn.

The first part of the address contained a rhetorical reference to surgery before anatomy was understood, and to what it had accomplished from the days of the ancients down to the present time, Special mention was then made to some of the noteworthy contributions which had been published during the past year, as "Internal Œsophagotomy," by Dr. H. B. Sands, of New York ; "Colotomy," by Dr. J. H. Packard, of Philadelphia ; "New Method of Treating Bone Cavities in Lower Part of Femur," by Dr. F. Lange, of New York ; "Cholecystotomy," by Dr. J. H. Mussey and W. W. Keen ; "Impacted Calculi in Ureter," by Dr. Henry Morris ; "Woven Wire Corset," by Dr. S. W. Smith, of New York ; "Successful Reduction of Dislocation of Sixth Cervical Vertebra," by Dr. J. Weed ; "Treatment of Wounds," by Dr. L. S. Pilcher, of Brooklyn ; and of surgical literature special reference was made to the last two volumes of

THE INTERNATIONAL ENCYCLOPÆDIA OF SURGERY,

Van Buren's "Lectures," edited by L. A. Stimson ; Dr. T. M. Markoe on "Sarcoma of Synovial Sheaths ;" Dr. Moses Gunn on "Philosophy of Reduction of Dislocations," and Dr. Walton, on "Antiseptic Surgery in Private Practice." The address closed with a beautiful tribute to the memory of the late Dr. Samuel D. Gross.

The address of the Chairman of the Section on State Medicine by Dr. E. W. Schauffer, of Missouri, was read by title and referred to the Committee on Publication.

The report of the Treasurer showed a balance in the treasury of $932.11, and an addition of one hundred and twenty-five members.

According to the new method adopted last year, the Librarian was authorized to send a report directly to the editor of the *Journal*.

Dr. J. M. Toner read the

REPORT OF THE COMMITTEE ON PUBLICATION

which included the report of the Board of Trustees of the *Journal*, in which it appeared that at the close of the second year

THE JOURNAL IS FREE FROM DEBT,

and that it commands an income which, if not diverted elsewhere, will enable the editor, with his corps of assistants, to make it one of the foremost journals in the land. The total income for the second year was $21,000, and the total expense, except editorial salary, twelve thousand odd dollars.

THE PUBLICATION OF THE JOURNAL WILL BE CONTINUED IN CHICAGO.

Dr. Davis will remain editor, having withdrawn his resignation at the earnest and unanimous request of the Board of Trustees.

In response to repeated calls, Dr. Davis addressed the Association and spoke at some length concerning the requirements to be met and the obstacles to be overcome in making a first-class medical journal, all of which could be accomplished by prudence and perseverance.

Dr. N. H. Reed, of Mansfield, O., offered the following resolution, which was adopted :

Whereas, There is no stimulus for original research at present in the Association,

Resolved, That a

FIRST AND SECOND HONOR PRIZE

be offered for the best and second-best paper in each Section at the next meeting of the Association and that three judges be appointed, no two of which shall be from any one State ; and said papers shall not occupy more than thirty minutes.

The following resolution, offered by Dr. J. B. Roberts, of Philadelphia, adopted by the Section in State Medicine, and referred to the Association, was read and laid upon the table temporarily :

Resolved, That the Section in State Medicine earnestly advocates establishing in every State and Territory

BOARDS OF MEDICAL EXAMINERS,

who shall examine all practitioners, and whose license shall be the only license to practice medicine.

On motion by Dr. J. M. Toner, of Washington,

THE REPORT OF THE COMMITTEE ON ERECTING A STATUE OF BENJAMIN RUSH

was taken from the table and read by the Secretary. The report closed with the following resolution, which was adopted, and the following committee appointed: Drs. A. L. Gihon, of Washington; Henry Smith, of Philadelphia; R. A. Kinloch, of Charleston; S. C. Gordon, of Maine; J. H. Murphy, of Tennessee; M. H. Henry, of New York.

Resolved, That this Association undertake to erect a statue in the city of Washington by members of the profession in the United States, and that the necessary funds be obtained by

SUBSCRIPTIONS LIMITED TO ONE DOLLAR,

and by voluntary donations from such others as may be interested in the matter.

The Secretary announced the following Committee on that Part of the President's Address relating to Forensic Medicine: Drs. I. N. Quinby, of New Jersey; C. Scott, of Cleveland, O.; W. W. Dawson, of Cincinnati, O.; F. E. Daniel, of Texas; J. V. Shoemaker, of Pennsylvania; Eugene Foster and H. F. Campbell, of Augusta, Ga.

Dr. R. A. Kinloch, Chairman, read the following

REPORT OF THE COMMITTEE ON NOMINATIONS,

which was adopted:

President—Dr. William Brodie, Detroit, Mich.

Vice-Presidents—Drs. Samuel Logan, New Orleans; A. Y. P. Garnett, Washington; Charles Alexander, Wisconsin; W. F. Peck, Iowa.

Permanent Secretary—W. B. Atkinson, Philadelphia.

Treasurer—Richard J. Dunglison, Philadelphia.

Librarian—C. H. A. Kleinschmidt, Washington, D. C.

Officers of Sections: Practice of Medicine—James T. Whittaker, Cincinnati, Chairman; B. L. Coleman, Kentucky, Secretary. *Section on Obstetrics*—S. C. Gordon, Maine, Chairman; J. F. Y. Paine, Texas, Secretary. *Section on Surgery and Anatomy*—Dr. N. Senn, Milwaukee, Wis., Chairman; H. H. Munn, Missouri, Secretary. *Ophthalmology, Otology, Laryngology*—Dr. Eugene Smith, Detroit, Mich., Chairman; J. Fulton, Minnesota, Secretary. *Diseases of Children*—Dr. W. D. Haggard, Tennessee, Chairman; Dr. W. B. Lawrence, Kansas, Secretary. *Dental and Oral Surgery*—Dr. J. H. Marshall, Illinois, Chairman; Dr. J. E. Baldwin, Illinois, Secretary. *Committee on State Medicine*—Dr. J. S. Rauch, Illinois, Chairman; Dr. F. E. Daniel, Texas, Secretary. *Committee on Necrology*—Dr. J. M. Toner, Washington, Chairman.

Judicial Council—Dr. R. A. Kinloch, South Carolina; D. D. Sanders, Tennessee; T. G. Richardson, Louisiana; D. A. Ketchum, Alabama; George Beard, West Virginia; J. M. Toner, District of Columbia; A. M. Pollak, Pennsylvania.

Place of Meeting—St. Louis, Mo., on the first Tuesday in May, 1886.

The following members were

ADDED TO COMMITTEE ON INTERNATIONAL CONGRESS:

Drs. D. A. Linthicum, Arkansas; George A. Ketchum, Alabama; A. R. Smart, Michigan; J. V. Shoemaker, Pennsylvania; F. A. Sim, Tennessee; J. W. McLaughlin, Texas; A. Y. P. Garnett, District of Columbia; S. C. Gordon, Maine; John S. Lynch, Maryland; Ellsworth Eliot, New York; X. C. Scott, Ohio; W. C. Dabney, Virginia; Nicholas Senn, Wisconsin; Robert Battey, Georgia; J. W. Dupree, Louisiana; W. E. Anthony, Rhode Island; R. D. Murray, Florida; E. P. Cook, Illinois; J. B. Hamilton, Marine Hospital Service; R. B. Cole, California; Charles Denison, Colorado; F. W. Beard, Indiana; D. W. Stromont, Kansas; L. P. Bush, Delaware; A. H. Wilson, Massachusetts; William Pierson, New Jersey; R. A. Kinloch, South Carolina; W. H. Watson, Kentucky; S. C. Gordon, Maine; E. French, Minnesota; N. F. Essig, Missouri; R. C. Moore, Nebraska; G. Baird, West Virginia; Surgeon-General Murray, U.S. Army; Surgeon-General Gunnell, U. S. Navy.

Dr. Quinby, of Jersey City, offered the following resolution, which was adopted:

Resolved, That the Committee appointed in pursuance of a resolution adopted by this Association, April 30, 1885, to constitute an addition to the original committee of seven, previously appointed, to invite and make arrangements for the meeting of the International Medical Congress, to be held in Washington, D.C., 1887, be and the said Committee is hereby authorized and empowered to select a Chairman and Secretary, and to fill all vacancies that may occur by death or inability to attend on the Committee, and to appoint the officers of the Congress.

The Committee met immediately to make preliminary organization.

Dr. Brodie resigned from the Judicial Council. Resignation accepted and referred to Committee on Nominations.

SECTION ON PRACTICE OF MEDICINE.

TUESDAY, APRIL 28TH—FIRST DAY.

Dr. Didama, of Syracuse, N. Y., Chairman, called the Section to order.

Dr. Bulkley, of New York, read a paper

ON CARBUNCLE.

He objected to incision, because of the danger from pus being absorbed, which does not occur when the carbuncle is allowed to open naturally. He was opposed to poultices, and gave calcium sulphite in quarter-grain doses in gelatine-coated pills every two hours, magnesia sulphate in laxative doses three times a day, and tonic doses of sulphate of iron; and an application of solid extract of ergot two drachms; oxide of zinc, one drachm; rose-water ointment, two ounces, upon lint, to the carbuncle, which reduces pain and cuts short the disease.

Dr. Hebbard, of Indianapolis, found that oleate of morphia, applied every two hours, cuts short carbuncle to a few days' duration. He did not incise.

Dr. Lynch, of Baltimore, indorsed Dr. Bulkley's plan, but applied dilute citrine ointment.

Dr. Shoemaker, of Philadelphia, did not incise carbuncle, unless there was a considerable quantity of pus. He indorsed Dr. Bulkley's treatment and did not get good results from oleates.

Dr. Savage, of Tennessee, painted a ring of collodion aronnd the carbuncle with good results.

Dr. A. F. Patte, of Boston, Mass., read a paper upon

THE PERCUTEUR: ITS USES IN DISEASES OF THE NERVOUS SYSTEM,

and exhibited an instrument.

Dr. N. Harvey Reed, of Mansfield, O., read a paper on

HYDATID TUMORS.

Dr. Jakins, of Iowa, in the discussion thought it strange that the hydatids should have occurred in the brain and not in the liver, and was inclined to doubt the correctness of the diagnosis.

Dr. Whitaker, of Cincinnati, thought the microscopic examinations should have been more complete before a diagnosis was made.

Dr. Whitaker, of Cincinnati, then read a paper entitled

AN ATTEMPT AT RADICAL TREATMENT OF TUBERCULOSIS.

He had in five cases injected one-eighth of a grain of bichloride of mercury into the consolidated portion of the lung daily, in five cases, but without favorable result.

The Section then adjourned.

WEDNESDAY, APRIL 29TH—SECOND DAY.

The first paper was on

THE HYPODERMATIC INJECTION OF OIL,

by DR. JOHN V. SHOEMAKER, of Philadelphia. Experimental and clinical observations have taught us that oils that cannot be swallowed, or are rejected by the stomach, can be absorbed by inunction and subcutaneous injection. Not only has the rapid and good purgative result of oil used hypodermatically been demonstrated, but its nutritive action when thus applied, has been shown to be valuable in debility, dyspepsia, scrofula, tuberculosis, and in certain diseases of the skin and nervous system. It is the quickest and best method of introducing oil into the system. It is an invaluable means of combating disease, particularly where more nutrition is required and also for those patients who are either unable to swallow oil, or who cannot absorb or assimilate it by the alimentary canal. Oil can be used subcutaneously alone or combined with other suitable agents that can be easily dissolved in it. It is a valuable menstruum for suspending in it other drugs for hypodermatic use. It can be given in connection with a suitable diet, and even with other medication by the mouth, or it can be used alone for alimentation. Oil deposited in this way in the tissues is absorbed, and is no doubt assimilated, and will alone keep up the nutrition of the body. For a purgative action one or two injections of a drachm or two of castor oil usually suffices, but for a nutritive effect the same quantity of one of the bland nourishing oils—*e.g.*, cod-liver or olive oil—should be administered two or three times daily.

In the event that alimentation is depending solely upon the injections they should be given about every two hours. For the purpose of giving oil hypodermatically, a large syringe provided with a needle of good calibre should be used and the instrument should have a capacity of from two to eight drachms. The injections can be made in almost any part of the body well provided with subcutaneous cellular tissue, into which the oil should always be thoroughly deposited. The points usually selected for the injections are the superior and inferior scapular and sacral regions, on account of the subcutaneous cellular tissue being especially abundant there. Injections can also be made in the arms, the chest front laterally, and back, the buttocks, and the legs. There is more or less irritation at the point of puncture of the skin, about the same as will be seen from the use of almost any other hypodermatic injection; sometimes there will also be some attending smarting, with redness and swelling and the formation of a nodular elevation, which usually disappears in from twelve to forty-eight hours, no induration or inflammation follows the injections provided the usual precautions are observed in using the hypodermic syringe properly, and the tissues in the person receiving it are in the normal condition.

SECTION ON SURGERY.

TUESDAY, APRIL 28TH—FIRST DAY.

The Section was called to order by DR. DUNCAN EVE, of Tennessee, Chairman, and Dr. Henry I. Reynolds, of Chicago, was elected Secretary, *pro tem.*

DR. JOHN B. ROBERTS, of Philadelphia, read a paper on

FALSE DOCTRINES IN THE TREATMENT OF FRACTURES,

referring first to errors by the invariable use of the primary bandage and by the use of passive motion too late or too early. He said splints were often left on too long; there was more damage done by letting it alone than by exploring in fractures of the skull. He also referred to fractures of the nose, clavicle, humerus, and elbow-joint. The use of the interosseous pad in the forearm he maintained did not do what was claimed for it. He believed that as a diagnostic point measurement was not of as much value in the lower extremities as was generally supposed.

The paper was discussed by Drs. Peck, of Iowa; Quinby, of New Jersey; Budd, of Missouri; Murphy, of Minnesota; Bird and Cook, of Illinois; Elliott, of Georgia, and Francis V. White of New York.

The next paper was by DR. VERITY, of Illinois, and entitled

THE TREATMENT OF COMPOUND FRACTURES BY FREE DRAINAGE AND WIRING OF BONES.

He claimed that no fragments should be removed unless they were sources of irritation, that all should be wired together and free drainage established. He related several very interesting cases, which he illustrated with drawings.

The discussion of the paper was postponed till the next session. The Section then adjourned until Wednesday.

WEDNESDAY, APRIL 29TH—SECOND DAY.

The meeting was called to order by the Chairman, DR. EVE, of Tennessee.

DR. P. E. ARCHINARD, of Louisiana, was elected Secretary *pro tem.*

DR. H. O. MARCY, of Massachusetts, read a paper entitled

DO WE FIND FROM MICRO-ORGANISMS IN ENCLOSED CAVITIES A HITHERTO UNSUSPECTED DANGER TO SURGICAL LESIONS?

He reported several interesting cases in which micro-organisms were found in ovarian fluids.

The paper was discussed by Drs. Byrd, of Illinois, Peck, of Iowa, and Hurst, of Illinois.

DR. SENN, of Milwaukee, Wis., then read

A PAPER ON THE SURGICAL TREATMENT OF CYSTS OF THE PANCREAS.

The paper was summarized in conclusion as follows: 1. Cysts of the pancreas are true retention cysts. 2. Cicatricial contraction, or obliteration of the common duct or its branches, and impacted calculi, are the most frequent causes of cysts of the pancreas. 3. A positive diagnosis of a cyst of the pancreas is impossible. A probable diagnosis between it and some other kind of cysts amenable to the same surgical treatment is adequate for all practical purposes. 4. The formation of a pancreatic fistula under antiseptic precautions recommends itself as the safest and most expedient operation in the treatment of cysts of the pancreas.

The next paper was by DR. RANSOHOFF, of Cincinnati, O., entitled

TWO OVARIOTOMIES ON THE SAME PATIENT.

It was discussed by Dr. Reid, of Ohio, and Dr. J. H. Warren, of Massachusetts.

The next paper was on

GIANT GROWTH OF THE LOWER EXTREMITIES.

DR. R. H. JENKINS, of Georgia, then read a paper entitled "Report of a Case of Necrosis of Tibia and Fibula of Ten Years' Duration—Operation and Recovery."

THURSDAY, APRIL 30TH—THIRD DAY.

The Section was called to order by THE CHAIRMAN, and DR. HENRY J. REYNOLDS, of Chicago, Ill., was elected Secretary, *pro tem.*

The first paper was by Dr. A. Y. GARNETT, of Washington, D. C., entitled

COLO-PROCTITIS TREATED BY HOT-WATER DOUCHE AND STRETCHING OR DIVISION OF SPHINCTER ANI.

It was discussed by Drs. Dawson, of Ohio, Ransohoff, of Ohio, Peck, of Iowa, and Byrd, of Illinois.

A paper by Dr. H. L. Getz, of Iowa, on

A NEW COMBINED TROCAR AND CANULA, AND ASPIRATING NEEDLE,

was referred to the Committee on Publication, as the writer was not present.

A case of fibroma of the scalp was presented by Dr. Owens, and discussed by Drs. Dawson, Kinloch, and Warren.

The Section then adjourned.

SECTION ON OBSTETRICS.

Tuesday, April 28th—First Day.

The Section was called to order, Dr. R. S. Sutton, of Pittsburg, Pa., Chairman.

Dr. William H. Wather, of Louisville, Ky., read a paper on

THE TREATMENT OF THE SECUNDINES IN ABORTION AND LABOR.

He referred first to the membranes of abortion during the first month, then to those of premature labor, then to those of labor at term. During the first and second months of fœtal life the fœtus and membranes are so closely connected that one cannot be expelled without the other. If the membranes can be removed from the vagina with the finger immediately, this should be done, but if necessary to go inside of the uterus they should be turned over for a time to nature. The dangers of the third stage are greatest of all.

Medical literature contains many instances of death from retained placenta and membranes.

Dilatation can be made with metallic or rubber dilators and the membranes should be removed by curette or forceps. A curette can be improvised if not at hand. If the uterus does not expel the placenta in thirty minutes, we should assist it by manipulation. If we forcibly remove the placenta sooner than fifteen minutes after the birth of the child, there is danger of coagulation not being completed.

Dr. Chadwick, of Boston, said that he always asked concerning the previous history of the woman, if she was a bleeder, or if she had gone through other abortions with no serious results. If a bleeder, he usually made active interference, fearing hemorrhage, otherwise he waited. In the later months, dilatation by the finger was the best.

Dr. Green spoke confirming Dr. Wather's experience.

Dr. Sinclair, of Boston, favored dilatation by the fingers. He explained the method which he inaugurated several years ago. He inserts one finger, and holds it quiet till the fibres of the uterus are exhausted, then inserts another and then another, occupying in the whole procedure half an hour.

Dr. Carroll, of Covington, Ky., thought the finger not only a good dilator but a good indicator.

Dr. Wather heartily approved of dilatation by the fingers in the latter months. In the first months he advised instruments.

Dr. W. W. Potter, of Buffalo, read a paper

ON PARAMETRIC ABSCESS,

and related a case in which there was the rapid formation of a large abscess, attended with improvement under the use of iodoform. He maintained that the expectant treatment of yesterday gave place to evacuation to-day, and that delay was always dangerous.

Dr. C. Fenger, of Chicago, read a paper on

CHRONIC PERI-UTERINE ABSCESS; ITS TREATMENT BY LAPAROTOMY.

If the abscess is deep or behind the uterus, laparotomy is often necessary. He used the thermo-cautery to make the incision. The antiseptic precaution should be employed. He preferred iodoform externally and boracic acid for injections. The advantage of laparotomy over vaginal operation was manifested by the fact that the former gave a better opportunity for reaching the seat of the trouble.

Dr. Geo. J. Engelmann, of St. Louis, spoke of the frequency of the cases and the necessity of recognizing them early, and then using active measures promptly. He thought temporizing

CAUSED MUCH EVIL.

Dr. Gordon, of Maine, thought prophylaxis all-important; half or two-thirds of the cases he believed the profession responsible for, especially the young doctors were too free with the uterine sound and nitrate of silver.

Dr. G. C. Reeve, of Dayton, O., reported a number of cases. He thought the young physician not always at fault. If he did suggest the knife he was discharged and another called in.

Dr. Potts said that the best way to evacuate was to dilate along the track of the needle. He agreed with Dr. Gordon in the harm done by the uterine sound.

Dr. Jaggard, of Chicago, spoke of the plan of Dr. Byford to dilate the anus and drain the abscess.

Dr. Sutton reported one case of laparotomy for pelvic abscess with good recovery.

Dr. George French, of Minneapolis, read a paper on

HOW SOON AFTER EXPOSURE TO SEPSIS MAY THE ACCOUCHEUR RESUME PRACTICE.

He dwelt on the crime of carrying the poison to a patient, and read a number of letters from authorities in England and on the Continent, some asserting time to be essential, others that a thorough cleansing and antisepsis was the desideratum.

Dr. Robert Battey, of Rome, Ga., thought a consciousness of the danger of carrying septic matter was one of the greatest safeguards. He believed time or ventilation had something to do with it.

Dr. Hoppler, of Vermont, thought cleanliness godliness itself in obstetrics.

Dr. French believed time salutary, but disinfection more important.

Dr. J. A. Y. Payne, of Galveston, Tex., reported a case of

ABDOMINAL TUMOR,

of the hard fibroid variety, of enormous dimensions. The following were the measurements when the case came to him: Epigastric, 50 inches; umbilical, 51 inches; hypogastric, 51½ inches. Ten days later the tumor had increased half an inch. One year later the measurements were 26¼ inches, 20½ inches, and 22 inches respectively. He used ergot, giving as much as ten grains hypodermically twice a day.

The Section then adjourned.

Wednesday, April 29th—Second Day.

Dr. N. J. Nunn, of Savannah, Ga., read a paper on

THE MULTIPLE SPECULUM UTERI AND AN IMPROVED DRESSING FORCEPS.

The speculum had five blades, and filled all the requirements of a Cusco, a Graves, and a Sims. The speculum and dressing forceps were exhibited.

Dr. G. Otto, of Arkansas, exhibited a speculum. It was first intended to be used only in the Sims position. He had found, however, that it answered equally as well in the dorsal. The connecting medium was entirely out of view.

Dr. J. Engelmann, of St. Louis, spoke concerning

THE IMPROVED TECHNIQUE IN GYNECOLOGICAL OPERATIONS, MINOR AND MAJOR,

and said, his manner of operating was similar in many ways to the European, though in some points original.

It was entirely different from the American way of operating. He claimed for it asepsis, or cleanliness, simplicity, and rapidity. The plan is to make operations on the vaginal tract under the hot vaginal douche, and use no sponge whatever. He has used no sponges for years. He showed a new Simon speculum, quite large and broad, stout and convex, which widens the vagina and draws it down by pressure in the perineum. He recommended asepsis in major and minor operations, and careful attention to details.

Dr. T. M. Healy, of Cumberland, Md., showed a speculum, the object of which was to do away with an assistant, which was very desirable in country practice.

Dr. Henry O. Marcy, of Boston, read a paper on the subject of "Speculi," which was not discussed.

Dr. Henry O. Marcy also read a paper on

THE RÔLE OF BACTERIA.

He had a number of years ago maintained in the Boston Medical Society that

DELIVERY SHOULD BE CARRIED ON WITH AS MUCH ANTISEPTIC PRECAUTION AS AN EXTENSIVE SURGICAL OPERATION.

He found then no supporters; now a number of leading schools taught that antiseptic injection should be made in every case as routine practice. In the majority of normal labors there is a solution of continuity, cervical, vaginal, or perineal. The physiological state is so distorted that it was akin to a pathological one. In his own practice he treats the womb as an infecting, suppurating wound.

Dr. French, of Minneapolis, was so entirely in consonance with the views of the writer that he could not criticise.

Dr. Hull, of Arkansas, did not think the essayist correct in considering the uterus as a subcutaneous wound. He thought the state of affairs quite different.

Dr. M. Gordon, of Portland, Me., said that

NO MAN WAS FIT TO PRACTICE MEDICINE WHO WAS NOT CLEAN.

He thought every man better off with a bath a day. Hot water was all that was necessary. You can find reports of as many deaths from carbolic acid and bichloride poisoning as you can from sepsis in the same time.

Dr. R. Beverley Cole, of San Francisco, Cal., spoke against the ideas expressed in the paper in the strongest terms. He defied anyone to show better results in midwifery since the introduction of antisepsis than before.

Dr. Kane, of St. Louis, and Dr. Stone, of Virginia, spoke in favor of antiseptic midwifery.

Dr. A. Reeves Jackson, of Chicago, read a paper on

VAGINAL HYSTERECTOMY FOR CANCER.

He quoted largely from authorities and tables, and drew the deduction that the mortality was so enormous that the relief gained from the operation was nil, and therefore he thought the operation was unjustifiable and should be abandoned.

As no one present had performed a vaginal hysterectomy for cancer the paper was not discussed.

The Section then adjourned.

Thursday, April 30th—Third Day.

Dr. E. Zink, of Cincinnati, read a paper entitled

EMMET'S OPERATION—WHEN SHALL IT AND WHEN SHALL IT NOT BE PERFORMED?

The Doctor went to great labor to compile a paper which treated of the subject in a most thorough and classic manner. He addressed a letter to twenty-five prominent gynecologists in this country and abroad, asking them twelve questions on the subject.

The sum of their answers he presented in tabular form. The number of cases reported operated upon was 4,945, and from the answers to the letters addressed to these gynecologists, from study, reading, and thought on the subject, together with his own experience, he drew a series of conclusions numbering in all twelve. No. 4 was, the operation should never be performed, *eo ipso* in cases of simple fissures or lacerations of first or second degree.

Dr. Harvey, of Indiana, opened the discussion. He thought that in many instances the pain was greater in slight tears than in large ones. Large tears eventually cicatrize and do not pain, small tears fissure and become very painful and tender. He likened them to fissure of the anus, and, contrary to Dr. Zink, thought they should be opened and cauterized.

Dr. Watson, of Louisville, said the doctor had omitted to state the fact that it was sometimes necessary to operate immediately.

Every case is an individual one. He thought operation contra-indicated if the case improved under treatment, and contrariwise if sterility or disposition to abortion persisted.

Dr. Gordon, of Maine, said that Dr. Emmet stated that he had never seen a case of epithelioma cervicis without laceration. Dr. Gordon thought every laceration should be operated upon, fearing epithelioma.

Dr. King, of St. Louis, confirmed Dr. Harvey's statement concerning small lacerations, which were more liable to develop cancer than the large ones. He thought Dr. Emmet very inconsistent in regard to operating on small lacerations and regarding the occurrence of epithelioma.

Dr. Aldrich, of Pennsylvania, thought every case should be operated upon. He had seen scratches on the cervix cause much trouble.

Dr. Hale, of Illinois, held the conservative doctrine, yet it was not always the little laceration which should be let alone.

Dr. Healy said that triviai lacerations do not skin over as had been affirmed.

Dr. Lewis, of New Orleans, had once thought every laceration should be operated upon. With greater experience he has become more conservative.

Dr. H. O. Marcy, of Boston, was glad to hear from gentlemen from all parts of this land that they were able to diagnose cervical lacerations. Our "masters" across the water are not so expert. He was more conservative now than five years ago.

Dr. Reid, of Ohio, said it had been claimed by the gentlemen that every woman who had had a child had a lacerated cervix. He had seen hundreds of women who had children and no laceration of the cervix.

Dr. Battey, of Rome, Ga., was not in favor of operating on every case.

Dr. Sutton, of Pittsburg, closed the discussion, Dr. Zink being obliged to go.

Dr. Gordon, of Maine, read a paper entitled

REASONS FOR AND RESULTS OF SOME CASES OF TAIT'S OPERATION.

He recounted a discussion he heard at Copenhagen, in which Sir Spencer Wells criticised the paper of Koeberle, of Strasburg, saying no woman should have her ovaries removed from symptoms alone, and not unless we could prove disease by the toueh. He gave the history of seven cases on which he had operated for symptoms alone, and found the disease and relieved the symptoms.

Dr. B. G. Heard, of San Antonio, Tex., read a paper on

INTRA-PERITONEAL ADHESIONS IN RELATION TO TAIT'S OR BATTEY'S OPERATION.

He thought that in many cases when Battey's operation was performed, it was only necessary to open the abdomen and remove the adhesions.

Dr. Battey, in discussing Dr. Gordon's paper, said many considered the field for his operation a very lim-

ited one. Sir Spencer Wells had used it but twice, Dr. Duncan but once.

The discussion was continued by Drs. Sutton, Gordon, Wather, Hedra, and Harvey.

Dr. Horatio Bigelow, of Washington, D. C., being absent in Europe, a paper by him entitled

NOTES ON SURGICAL GYNECOLOGY IN THE BERLIN CLINICS,

was read by Dr. Sutton. The gentleman being absent, the paper was not discussed.

Dr. W. A. Jaggard, of Chicago, read a paper entitled

THE RING OF BANDL.

The paper was a very elaborate one, with numerous anatomical photographs. He concluded as follows: "The state of our knowledge is not at present such as to warrant us in a positive decision, but the weight of testimony is in favor of the existence of the ring of Bandl."

Dr. T. A. Reamy, of Cincinnati, being absent, his paper on "Treatment of the Pedicle," was not read.

The Section then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 27, 1885.

Daniel Lewis, M.D., President, in the Chair.

THE INFLUENCE OF SEA-VOYAGING UPON THE GENITO-UTERINE FUNCTIONS.

Dr. J. A. Irwin read the paper, which was based upon a number of years' experience as surgeon on board ships plying between the ports of America and Europe, and also between Europe, India, Africa, and Australia. He had also studied carefully the literature of the subject.

The importance of the subject of the influence of sea-voyaging upon the genito-uterine functions was evident from the fact that it had long been observed that serious disturbances often attended such a change, and from the fact that transatlantic travel was becoming yearly more enhanced. It was, therefore, rather surprising that the subject had not been more carefully investigated. The observations of one surgeon, however great, could go but a short distance in establishing rules with regard to the influence of sea-voyaging upon the genito-uterine functions; but the author hoped that, on reading the record of his observations, other physicians would be led to supplement them by their own experience.

While on shipboard Dr. Irwin had made records of 104 pregnancies, 11 parturitions, 3 miscarriages, and 451 menstruations or misperiods among women in whom the function was usually regular.

THE EFFECT OF SEA-VOYAGING UPON THE MENSTRUAL FUNCTION.

In order that the value of the figures regarding the menstrual function might not be overrated, the author said that 288 of the 451 observations were based upon the inquiries of the stewardess among the passengers under her charge. They were thought to be reasonably reliable. Of the 288 women included in her returns, all of whom were supposed to be non-pregnant and menstruated normally previous to the voyage, 21 passed the period while on board without menstruating; 43 menstruated before the period, and 224 menstruated at the proper period, while 23 complained of pain, and in a few instances of increased or diminished flow, while 201 noticed absolutely nothing unusual which could be attributed to the voyage.

Turning to his own 163 observations, 13 of the women passed the period on board without menstruating, of whom 11 experienced more or less molimen; 51 menstruated before the usual period, 99 at the proper period. Of these 47 complained of unusual discomfort, accompanied in 37 instances with increased and prolonged flow, and in 2 with diminished discharge. Of the 13 who passed the period, 3 were on board at the second period; in 1 of the 3 menstruation was almost normal; in the second the result not known, and in the third the process was increased and prolonged, but at the two subsequent periods she had complete amenorrhœa. Thus, of the 163 cases observed by himself only about thirty-one per cent. performed the function of menstruation as normally as on land. These women were usually of a more refined class than those observed by the stewardess.

In one of the cases the patient was a resident of New York, who had kept an accurate observation of her menstrual periods for fourteen years, during twelve of which she was a widow. With the exception of four periods, the only ones which occurred at sea, and another, which might otherwise be accounted for, she always menstruated with perfect regularity. Every flow which took place on shipboard departed from the normal standard.

It was a more difficult task to explain facts observed, and to deduce from them principles applicable to practice. This difficulty was increased by our ignorance and conflicting opinions regarding the real nature of menstruation. The special conditions of an ocean voyage which might be supposed to exercise an influence upon female habit might be classed under three heads: Psychical, dependent upon the novelty of the situation and the apprehension of danger; aërial, dependent upon some special quality of the sea air; and, lastly, motional, as a direct result of the movements of the vessel.

There could be no question as to the effect of strong mental impression upon menstruation. It was perfectly tenable to suppose that mental influence occasionally played some part in the disturbances under consideration, especially in those cases, by no means frequent, of the sudden arrest of the flow in women who had embarked while actually menstruating. It could not, however, be regarded as a principal cause, since women who suffer much at this time often have not a particle of fear, and would thoroughly enjoy sea-life but for its unpleasant effect in this direction.

However acquired, sea-air has some extraordinary hygienic potency, which has been recognized in every age of medicine. It held a distinguished rank among the remedies of antiquity.

It was also clear that the motion on board a ship disturbed in some way the established habits of the economy, and the author thought the credit of having demonstrated the true pathology of sea-sickness, or rather of motion sickness, had now been pretty generally conceded to him, his views having been published in 1881. The ordinary form of sea-sickness, or that form caused by the easy gyrations of a large ocean steamer, was essentially a disturbance of equilibration, the initial lesion being in the semicircular canal. This soon led to dizziness, followed by nausea and vomiting.

Some authors claimed that the motion of the ship exercised a peculiar influence upon the ganglionic system of nerves, and produced certain other effects, but by far the more striking of these effects was that which formed the subject of the essay. It was Dr. Irwin's conviction that menstrual disturbances on shipboard were almost entirely due to the motion of the vessel, and that the constant tendency of this motion was to increase the blood-supply to the pelvic organs. The result differed in degree from a slight and sometimes beneficial circulatory stimulus to a positive and dangerous engorgement, but under all circumstances the primary influence is unquestionably toward congestion.

It would be seen that a sea-voyage might disturb the menstrual habit in almost every conceivable direction—in its periodicity, duration, amount of excretion, and discomfort. The particular effect most constant in each

case was determined by the constitutional habit of the individual, the relation of the last period to the date of embarkation, the length of the voyage, and fortuitous conditions.

Regarding periodicity, a premature return of the flow was far the most frequent effect. There may be a return of the sanguineous discharge at any time during the intra-menstrual epoch, but it is more liable to return if the voyage be undertaken during the first ten days following normal menstruation. On the other hand, complete and passive amenorrhœa for one or more periods after landing is a frequent result of the Atlantic transit.

Of the various effects of sea motion upon menstruation it was unfortunate that none was more universal than an aggravation of whatever discomfort is ordinarily associated with this process. In some women painful menstruation is experienced for the first time at sea. In the author's opinion the statement may be accepted as universally true that in every type of dysmenorrhœa the discomfort experienced is increased, certainly at the first, and usually at subsequent menstruations during the voyage. If there were any exception to this rule it must be in certain neurotic states. Dr. Irwin offered some explanations for this phenomenon, based upon prevalent theoretic views concerning menstruation, ovulation, etc.

A sea-voyage was likely to hasten puberty or the first menstrual flow. Some women who were undergoing the climacteric epoch also had a return of the flow during a sea-voyage.

The aphrodisiac influence of a sea-voyage was generally accepted, and it was easy to understand that an increased blood supply to the genito-uterine system, should excite the sexual instinct. But there might be other conditions than the mere influence of the voyage at sea itself which would tend to produce this result.

An ocean-voyage should be regarded as a potent emmenagogue, having, in addition to the special influence mentioned, a well-marked tonic, alterative, and sedative influence. With these characters it is entitled to head the list of therapeutic agents of similar effect, and should no longer be prescribed empirically, but with a definite object in view. There are many cases in which this local and perhaps constitutional influence was indicated.

In the conditions included under the term chloro-anæmia with amenorrhœa and retarded sexual maturity, certain forms of leucorrhœa and uterine hysteria, in undeveloped school girls, a typical case of which class had been described by Dr. Emmet, in this class of cases a sea-voyage would be indicated.

Again, there were many conditions of the genital organs, which, if not positively interdicting a sea-voyage, demanded special prophylaxis and skilful attention while on board the vessel. Almost every form of uterine and ovarian disease became worse while at sea. Uterine displacements were unfavorably affected during the voyage.

The treatment of uterine troubles during ocean transit should be conducted upon general principles.

The influence of sea-voyage upon utero-gestation was sometimes to produce abortion or early delivery. The vomiting attending sea-sickness was more violent than that of morning sickness, and was more likely to produce miscarriage. There was no uniformity of opinion upon this point, but it was the author's opinion that pregnancy, especially during the latter months, predisposed to, and always aggravated, the most distressing features of sea-sickness.

Sea-sickness invariably perverts or suspends lactation.

Dr. C. C. Lee said his experience regarding the influence of a voyage at sea upon genito-uterine disorders was limited. He agreed in the main with everything which Dr. Irwin advanced. In the first place, concerning congestion, he had not known an exception to the general rule that sea-sickness, or the derangement of innervation attending sea-sickness, increased pelvic congestion and the tendency to metrorrhagia and menorrhagia. He had not known of a case which had come under his observation in which a voyage at sea had caused miscarriage. He had never seen women or girls suffering from chlorosis or amenorrhœa benefited in the slightest degree by a sea-voyage. On the contrary, delicate chlorotic women were on the sea in crossing the Atlantic only a short time, and during that time being all the while sick, their condition seemed to be made worse rather than better. But there might be other conditions of ill-health in which a change of climate or conditions attending a voyage at sea would be of benefit. A long sea-voyage might be of greater benefit to the patient suffering from amenorrhœa or chlorosis, while it might prove injurious to women of plethoric habits, or who, either from displacements of the uterus or from previous peri-metritis or uterine tumors, or from habit, have been subjected to metrorrhagia or menorrhagic flow.

Dr. B. F. Dawson had seen one case of dangerous increase of the menstrual flow in a woman who had gone to sea while mourning the loss of an only daughter. He had also seen three cases of amenorrhœa produced by a sea-voyage, the cause being the mental impression produced by the sea-voyage, and not by sea-sickness.

Dr. O'Dwyer had been surgeon on board sailing vessels about thirty years ago, and had had opportunity to witness the effect of a long voyage upon the genito-uterine functions. It was not uncommon for mothers on the voyage to come to him with the statement that their young daughters did not menstruate, and Dr. O'Dwyer found little benefit from treatment in bringing about the flow. He had recently also gone as surgeon on one trip of an Atlantic vessel, and had made special inquiry as to the influence of the voyage on the sexual instinct, and almost invariably it was found to be enhanced.

Dr. Jacobus mentioned instances of amenorrhœa resulting from a sea-voyage becoming manifest after the passengers had come to land. No treatment in his experience had been of benefit, but the flow would return in the course of from three or four months to nine months.

Dr. McLaury had observed the same fact, and the women who thus suffered from amenorrhœa after a sea-voyage attributed it to the voyage.

Dr. Baruch had also observed the same fact, and had derived the greatest benefit in this form of amenorrhœa from permanganate of potassium.

Dr. Laurence Johnson had observed this form of amenorrhœa in persons who had landed in this country from Europe, and said it had been the custom at the Demilt Dispensary to call it marine amenorrhœa. It was painless, and always disappeared in the course of some months.

Dr. Bracklow had derived benefit from apiol in the amenorrhœa following a sea-voyage.

Dr. G. H. Butler mentioned an instance in which the patient menstruated normally only while at the sea-side, and it was her custom, therefore, to make her visit at the salt-water resorts as long as possible.

Dr. Irwin closed the discussion, thanking the gentlemen for the kind attention given to a lengthy paper, and for the corroborative evidence which the discussion lent in support of the truthfulness of the observation and inferences drawn therefrom recorded in the paper.

The Society then adjourned.

Night-sweats.—Professor DaCosta says that in the treatment of the night-sweats of phthisis ergot is preferable to atropine, being more permanent in its effects, and has the additional merit of not producing the dryness of the throat which so frequently follows the administration of atropine. He would give gr. ij. of ergotin ter die, the last dose given at bedtime.—*College and Clinical Record.*

Boiling Milk for Five Minutes destroys the tubercle bacilli if any are present, according to Prof. G. Sormani.

AMERICAN SURGICAL ASSOCIATION.

Annual Session, held at Washington, D. C., April 21, 22, 23, and 24, 1885.

(Concluded from page 468.)

THIRD DAY—THURSDAY, APRIL 23D—MORNING SESSION.

THE following officers were elected:

President—Dr. Moses Gunn, of Chicago.

Vice-Presidents—Drs. Christopher Johnson, of Baltimore, Md., and Thomas P. Russell, of Baltimore, Md.

Secretary—Dr. J. R. Weist, of Richmond, Ind.

Recorder—Dr. J. Ewing Mears, of Philadelphia, Pa.

Treasurer—Dr. J. H. Brinton, of Philadelphia, Pa.

Dr. L. McLane Tiffany, of Baltimore, was added to the Council.

The next meeting is to be held at Washington, on the Wednesday preceding the meeting of the American Medical Association. Chairman of the Committee of Arrangements—Dr. J. S. Billings, of Washington, D. C.

Members elected: Drs. J. Edwin Michael, of Maryland; Roswell Park, of Buffalo, N. Y.; W. H. Carmal, of Connecticut; J. Ford Thompson, of Washington, D. C.; Theodore R. Varick, of Jersey City, N. J.

The following Honorary Members were elected: Sir James Paget; Mr. John Eric Erichsen; Sir Joseph Lister; Professors Thomas Annandale, of Edinburgh; Frederic Esmarch, of Kiel; Von Langenbeck, of Berlin; Volkmann, of Halle; Czerny, of Heidelberg; Billroth, of Vienna; Von Nussbaum, of Munich; Verneuil, of Paris; Ollier, of Lyons.

DISCUSSION ON DR. WARREN'S PAPER.

DR. SENN thought that the external callus in the specimen shown was due largely to the injury produced by ligation and by septic changes; in reference to presence of muscular tissues in cicatrices, he considered it against analogy, and thought they might be due to displacement of pre-existing cells.

DR. WARREN, in reply, said that the amount of injury had much to do with the amount of external callus, but it had been observed there was the least amount of injury, where antiseptic precautions had been employed. In reply to another question he said that the thrombosis took no part in the cicatrization, but it served as a protection while the healing process was going on. It might be called the provisional callus, or the first stage of the internal protective callus.

The paper was further discussed by Drs. Gunn, Moore, and Prewit.

DR. J. W. S. GOULEY read a paper which considered: 1, The determination by physical exploration of the size of the hypertrophied prostate, and the character of the obstruction to urination; 2, the circumstances under which medicinal treatment possesses value; 3, the selection of catheters; 4, certain accidents of catheterism, especially false routes; 5, evacuative catheterism, its good effects, and its dangers; 6, vesical irrigations to combat cystitis, their use and abuse; 7, prostatotomy and prostaectomy, their indications and contra-indications.

DRS. GROSS and PREWIT fully indorsed the views of Dr. Gouley in regard to the management of retention of urine from obstruction due to enlarged prostate.

DR. E. M. MOORE stated that he had employed with much success, in those cases where there was contraction and much irritability of the bladder, what he called the moral treatment. This consisted in directing the patient to resist the desire to urinate, as long as possible. In this way the time between each urination might be prolonged to four hours.

DRS. MOSES GUNN and GOULEY had also employed this method. The Society then adjourned.

AFTERNOON SESSION.

DR. ERNST, of Boston, gave a demonstration of a number of culture-tubes containing micrococci from perinephretic abscess, erysipelas, pyæmia, and so on. These experiments had been made to confirm those of Rosenbach. The doctor claimed no originality in their performance. A microscopical exhibition of the bacilli of a number of diseases were made. He said that he should continue these experiments, and intended to perform a number of inoculations.

DR. WARREN referred to the clinical aspects of some of the cases from which the micrococci exhibited by Dr. Ernst had been obtained.

DR. GROSS moved that Dr. Ernst be invited to prepare a paper, giving the results of his experiments, to be read at the next meeting of the American Surgical Association.

The next paper was entitled

AN EXPERIMENTAL AND CLINICAL STUDY OF AIR EMBOLISM.

A paper on this subject was read by DR. N. SENN, of Milwaukee, Wis., in which the following points were touched upon:

1. The presence of adventitious air in the vascular system during life gives rise to air embolism.

2. Each air embolus constitutes a mechanical source of partial or complete obstruction to the flow of blood in the vessel in which it is located.

3. Aspiration during the inspiratory movements of the chest is the direct or exciting cause of the ingress of air into a wounded vein or sinus.

4. Elevation of the head is the sole predisposing cause of the entrance of air in wounds of the superior longitudinal sinus.

5. In veins the predisposing causes consist in (*a*) elevation of the part wounded; (*b*) pathological or anatomical conditions which prevent collapse of the vein when it is wounded.

6. Insufflation of a fatal quantity of air into a vein produces death by (*a*) mechanical over-distention of the right ventricle of the heart and paralysis of the diastole; (*b*) asphyxia from obstruction to the pulmonary circulation consequent upon embolism of the pulmonary artery.

7. Insufflation of the same quantity of air into arteries is less dangerous than when introduced into veins. When death is produced in this manner, it results from (*a*) acute cerebral ischæmia; (*b*) secondary venous air embolism; (*c*) intense collateral engorgement of the vessels of the brain and spinal cord, the manner of death being determined by the amount of air injected and the direction in which the injection is thrown, as well as the time which has elapsed between the operation and the fatal termination.

8. Air injected into arteries is readily forced through the systemic capillaries into the venous circulation and right side of the heart by the powerful contractions of the left ventricle.

9. An air embolus of the pulmonary artery is relieved in a comparatively short time, provided the contractions of the right ventricle continue unimpaired for a sufficient length of time to force the air through the pulmonary capillaries into the general circulation.

10. The prophylactic treatment consists in proximal or double compression or ligation of the vein which is endangered by the operation.

11. The indirect treatment has for its objects (*a*) prevention of the admission of air; (*b*) administration by inhalation or hypodermatic injection of cardiac stimulants; (*c*) venesection.

12. The direct or operative treatment by (*a*) puncture and aspiration of the right ventricle; (*b*) catheterization and aspiration of right auricle, which is proposed to obviate the direct cause of death by the removal of air and spumous blood, thus relieving directly the over-distention of the right ventricle, and at the same time to guard against a fatal embolism of the pulmonary artery.

13. The results obtained by experiments on animals

warrant the adoption of the operative treatment of air embolism in practice, as a last resort, in all cases where the indirect treatment has proved inadequate to meet the urgent indications.

The Association then went into executive session.

FOURTH DAY—FRIDAY, APRIL 24TH—MORNING SESSION.

ASPIRATION OF LARGE ABSCESS.

DR. GORDON, of Portland, Me., was introduced by Dr. Moore, and described a case which he had seen a short time ago. In a case of pelvic abscess he had twice aspirated, removing a large quantity of pus. Aspiration was again required. The apparatus employed was one which could be used either for aspirating or for condensing, according to the manner of attaching the tube. The assistant, who was not familiar with the working of the instrument, attached the tube to it so as to condense the air in the bottle. The needle was introduced into the abscess cavity, the connection made, and a large amount of air escaped into the cavity. The patient gave a scream and in a minute was dead. It had proved impossible to secure a post-mortem examination, but the speaker thought that there could be no doubt as to the nature of the accident.

DR. NANCREDE said that it had been noted that in the horse large quantities of air were required to produce a fatal result. This had been ascribed to the greater power of the right ventricle. In his opinion it was better explained by the larger size of the pulmonary capillaries allowing the spumous blood to pass through them. Death he thought was not a simple matter in these cases. In the instances cited by Dr. Senn, where a large amount of air had been injected, the heart was no doubt paralyzed by the distention. But in surgical practice the accident does not occur under such circumstances. A small quantity of air enters a vein and suddenly altering the specific gravity of the blood, interferes with its passage through the pulmonary capillaries and leads to ischæmia of the brain and want of blood in the respiratory centres.

In operating in regions where there was danger of the entrance of air into veins, he adopted certain precautions, as ligating or applying pressure to the vessels, and in the removal of tumors in such situations he was always careful to compress or tie the veins before dividing the last attachments of the growth.

In regard to direct treatment of the accident, he recommended artificial respiration in the recumbent position, with the ordinary measures of the inhalation of ammonia and the hypodermic injection of ether. In addition to these, he recommended the hypodermic use of sulphate of atropia, which stimulates the respiratory centres, and as a secondary action causes dilatation of the pulmonary capillaries, thus favoring the circulation of the altered blood.

DR. SENN being absent was given permission to have his remarks printed with the Transactions.

DR. P. S. CONNER, of Cincinnati, read a paper on

THE ETIOLOGY OF TETANUS.

In opening his paper, the speaker referred to the great desirability of a more thorough knowledge of this disease as bearing on its more successful treatment. Two classes of cases are embraced under the general head of tetanus. In one class the spasms first affect the injured part, while in the second, the spasms primarily involve muscles whose nerves arise in the medulla oblongata. There can be little doubt that the seat of the disease is in the medulla oblongata. It has not been determined whether the disease is brought about by the nerve, by the blood current, by extension of inflammation, by reflected irritation, by septic changes, or by the presence and development of micro-organisms. These different views were taken up and discussed at some length, and the probabilities were considered to be in favor of the view that attributes the disease to the absorption of septic matters from the wound.

During the reading of the paper the doctor made the interesting statement that in 16,000 foot injuries occurring during the late war, there were only 57 cases of tetanus, while in 12,000 hand injuries there was not one case of tetanus reported.

In conclusion, the speaker stated that the object of his paper was not to advance any particular theory, but simply to elicit discussion which might serve to throw some light upon this obscure affection.

DR. MOORE asked if the reason for the frequent occurrence of tetanus had been investigated.

DR. CONNER had considered these cases, but he had attributed them to the character of the wound leading to retention of the discharges, and not to any peculiarity in the powder employed.

DR. PREWIT referred to the fact that in some cases the disease ran a mild course, and he described two cases in which the affection had appeared some time after the accident. Both of these cases were treated with bromides and chloral, with the administration of Fowler's solution in five-drop doses repeated every three hours and continued for two weeks. These cases seemed to exhibit a marked tolerance for this remedy. Both of these patients recovered, although one, a man who had been wounded on the right arm, suffered with paralysis of the flexor muscles of the left foot. He was inclined to accept the view that the disease was due to a micro-organism.

DR. MEARS referred to cases coming under his observation where the disease had followed injuries of the hand and foot, and one case in which it followed amputation of the arm, in which the median nerve had been ligated.

DR. WEIST described one case of tetanus following gunshot injury of the hand which he had seen while in the army. In private practice he had within the past two years seen three fatal cases of tetanus following injuries of the hand.

DR. TIFFANY referred to the great fatality following injuries produced by the toy pistol, and stated that he had had the explosive carefully examined by a chemist, but with negative results. The black race, he said, were very prone to the occurrence of tetanus, and this fact, he thought, was against the idea that tetanus was due entirely to reflex nervous disturbance. He thought that something more was needed.

DR. MEARS had also had the fulminate examined, with the same result as obtained by Dr. Tiffany. He had come to the conclusion that the explanation was to be found in the cartilage, which was broken to pieces and imbedded in the wound.

DR. NANCREDE stated that most of the cases which he had seen had been cases of trivial injury, and he enumerated a number of accidents after which tetanus had appeared. He had seen only two cases of acute traumatic tetanus recover. Many plans of treatment had been employed without avail. Marked relief was afforded in one case by nitrate of amyl.

DR. GUNN could recall but three recoveries in cases coming under his notice. In two cases recovery followed nerve-stretching, in the third case it followed amputation and the use of calabar bean. It had been frequently noted, he said, that if cases lived until the tenth day they usually recovered. This might be formulated thus: The fatality will be in direct ratio with the acuteness of the attack.

DR. BRIGGS stated that, in his opinion, predisposition was an important element in the etiology of this affection, and described a case illustrating this point.

DR. CONNER said that all that he had heard had tended to confirm the humeral theory. He thought that a strong point against predisposition playing an important part in the causation of tetanus was the fact that many of those

who were afflicted with the disease had, on previous occasions, received severe injuries without the appearance of any indications of tetanus.

"The Immediate Cure of Fistula in Ano," by Dr. Stephen Smith, of New York, was read by title.

A paper entitled

A CASE OF CHOLECYSTOTOMY,

by Dr. C. T. Parkes, of Chicago, was read by Dr. Moses Gunn.

The patient, a lady, twenty-nine years of age, had long suffered with symptoms of obstruction of the common bile-duct. All forms of medicinal treatment had been employed without benefit. An operation was recommended and acceded to. An incision was made over the position of the distended gall-bladder, and the organ was brought into the wound and aspirated. This removed a quantity of mucoid fluid tinged with bile. The gall-bladder was then secured to the external incision and opened freely. The finger was introduced, but no calculi could be found. The wound was dressed antiseptically and not disturbed for four days, the patient doing well. When the dressing was made, a probe passed into the gall-bladder detected a stone. Two were removed on this occasion, and a few days later five more were found. They were all small, averaging about a grain in weight. The patient rapidly recovered from the operation, and was relieved of the pain and other symptoms complained of, but the bile did not escape into the intestine. A second operation was therefore performed, four weeks after the first. The external incision was extended downward, and the attempt to pass a small bougie through the common duct was made without success. A No. 10 (Frère, French) sound was then carried through the cystic duct into the duodenum. From this time the bile escaped freely into the bowel, and the fistulous opening rapidly healed.

Dr. Mears spoke of the difficulties of diagnosis in some of these cases, and of the necessity for the surgeon of carefully studying this subject. He then spoke of other conditions, such as inflammatory affections of the lining of the duct, causing obstruction, tumors, malignant disease of neighboring parts pressing on the duct, abscess of the gall-bladder, and impacted calculi, in which the operation is indicated.

Dr. Prewit described two cases in which the distended gall-bladder could be distinctly outlined. One was the case of a man, seventy years of age, who had never exhibited any signs of gall-stones, who was suddenly attacked with pain and collapse. Palpation showed that the gall-bladder was distended and filled with calculi. The patient did not rally, but died in collapse. At the autopsy a large number of gall-stones were found.

In another case of what has been termed dropsy of the gall-bladder, the gall-bladder extended to the level of the umbilicus. It was tapped, and a pint of mucoid fluid with very little trace of bile was removed. Operation was proposed, but refused.

A paper on

PHOSPHOROUS NECROSIS OF THE JAWS

was read by Dr. J. Ewing Mears, of Philadelphia.

After an elaborate review of the whole subject of phosphorous necrosis, the speaker reported sixteen cases which had been under his care and presented the specimens removed.

The following conclusions were reached:

1. That phosphorous necrosis of the jaws is a local expression of the constitutional condition produced by the inhalation of the vapor of phosphorus and by particles of the agent taken into the system with the food by operatives in match factories, who do not give proper attention to cleanliness of the hands.

2. That the introduction of the agent into the system is, as a rule, very gradual, and in such small quantities as to avoid the production of symptoms of acute poisoning. That in this way the chronic toxic condition of the system is induced, characterized chiefly by disintegration of the red blood-corpuscles and fatty degeneration of the arterial coats.

3. That the toxic condition precedes the development is shown by the fact that the disease does not attack operatives recently exposed to the action of the agent, but those who have been exposed for a period of years.

4. That examinations of teeth of operatives have shown that many who have a condition of caries, and that many who have returned to work immediately after the extraction of teeth, have enjoyed immunity from the disease, showing that the agent has not attacked the periosteal tissue thus exposed. (In one case, the disease did not appear until three months after labor in the factory had ceased.)

5. That individuals vary in their susceptibility to the action of the poison; for this reason many suffer immediately with symptoms of acute toxic conditions, such as nausea, vomiting, etc., and are compelled to abandon work in the factories.

6. That the conditions under which experiments have been made on animals to prove the absence of the disease until exposure of the periosteum and peri-alveolar tissue was affected, were not similar to those to which operatives in match factories are subjected.

7. That treatment of the disease in the primary stage in the manner outlined is efficient and prevents its progress.

8. That the antidotal powers of turpentine have been established, both in neutralizing the effects of the poison upon operatives during their work, and also in the treatment of the early stage of the disease.

9. That the disease is to be prevented among operatives by the adoption of thorough methods of ventilation, stringent rules with regard to cleanliness, and the free disengagement of the vapor of turpentine in all the apartments of factories in which the fumes of phosphorus escape.

The discussion was participated in by Drs. Moore, Nancrede, and Mears.

In a paper read by Dr. J. Ewing Mears, of Philadelphia, on an

APPARATUS FOR RAPID ANÆSTHESIA,

a device consisting of three parts was described. This had been devised and used by Dr. Mears in August, 1884. It consists of a bottle to contain the ether, a metallic mask to cover the mouth and nose, and a rubber tube connecting the two. The bottle of ether is placed in warm water, and the vapor of the ether passes in a concentrated form to the mouth-piece. Its flow is regulated by a stopcock. In this way it was claimed anæsthesia had been produced in less than one minute. The apparatus could be used in another way, by attaching the bottle directly to the inhaler. In this way the supply of ether could be kept up without the necessity of removing the inhaler from the face.

The Committee on Publication were authorized to have the vignette of the late Professor S. D. Gross attached to the seal of the Association.

The thanks of the Association were tendered the retiring officers and the Committee of Arrangements.

Brief remarks were then made by the President-elect and by the retiring President.

The Association then adjourned.

For Leucorrhœa.—The oil of erigeron possesses other very valuable properties—it is a most excellent remedy for leucorrhœa; indeed, I should place it next to iron, the most valuable of all our remedies for this trouble. There are many cases of leucorrhœa associated with plethora—here iron is contra-indicated, and the oil of erigeron is the most suitable remedy, though in anæmic cases it is equally effective.—*J. K. Shirk, M.D.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

COMPARATIVE ANATOMY AT THE PATHOLOGICAL SOCIETY —THE POISONS BILL—THE SOCIETY FOR THE STUDY OF INEBRIETY—SANITATION IN EGYPT—MEDICAL MISSIONS—HEALTH IN AFRICA—DEATH OF DR. SIDNEY COMBER.

London, April 14, 1885.

At the last meeting of the Pathological Society comparative pathology was again to the front. Dr. Norman Moore showed tuberculous kidneys from an ox. Bacilli had been found in abundance in both kidneys, and they agreed in form, size, and method of staining with those found in tubercle in man. The tuberculous part of the kidneys was nowhere broken down, but showed many zones of calcification. Dr. Dickinson described an epidemic of renal disease which had occurred in a herd of short-horn oxen on a farm in Oxfordshire. About half of the oxen were attacked, and the disease was fatal in almost all the cases. The urine was loaded with blood, and there were enormous casts. He had examined the kidney of one ox which had survived the attack of renal disease; it was in a state of typical interstitial nephritis.

The Poisons Bill is being actively opposed by the trade journals and other agencies.

The Society for the Study and Cure of Inebriety now has two hundred and seventy-nine members. Its members are not necessarily abstainers. A large number of medical men in this country are now total abstainers. The total number is variously estimated, but I think one thousand is not far from the mark. The profession now numbers twenty-five thousand registered members in Great Britain and Ireland, so this shows a proportion of about four per cent. Temperance men claim that a tenth (three millions) of the entire population are teetotallers.

Mr. Ernest Hart's letters in the *British Medical Journal* are throwing some light on the unsanitary sanitary legislation in Egypt, and the miserable condition of the medical school in Cairo. The dissecting-room he characterizes as "a loathsome farce," and he remarks, with scathing contempt, that the students learn by rote from antiquated Arabic books like school board children. Mr. Ernest Hart has the reputation of being able to smell out a rat as quickly as any one. He attracted some attention at the beginning of his career as a journalist by the vigorous onslaught he made on the abuses practised under the Poor-Law Board.

Medical missions have hardly received their due share of attention at the hands of the profession. Many of our societies now try to give their missionaries some medical training, especially when going to break new ground where civilization has not yet extended. Qualified medical men are also always acceptable as missionaries. I believe one society sends medical men only. I do not think the subject has been as much before the profession as it might be. I do not mean by this that medical men should become missionaries. A man naturally wishes to pursue the profession for which he has been educated, and medical men who are suitable for the work and are willing to go to the mission field, are not likely to be found in numbers. But many young doctors not yet settled in life might be willing to go abroad for a few years as the "medical officers" of the missionary society. They would be simply required to perform the duties of their own profession. A personal friend, now home from the Congo, who has travelled all through that region during the past eight years, frequently meeting Stanley in his explorations, tells me that the field for practice is enormous and that large surgery can be had *ad libitum*. Of course, I refer to the natives, who usually flock to the stations to be treated for "all the ills flesh is heir to.' The opportunities of studying botany and natural history, too, are not to be despised. I understand that the proposal to employ paid medical officers is about to be laid before one of our leading missionary societies, now actively engaged in Central Africa, and may perhaps lead to something. Of course, only a small salary could be paid, but there are many young men now eating out their hearts waiting for practice which cometh not, who would be only too willing to join a missionary party and form part of the advanced guard of civilization for a year or two. Hardships would have to be endured and the native fevers gone through, but I do not know that these would be worse than the spears of the Soudanese or the cannon of the Russians. Our surgeons have faced the first; they will be equally ready to confront the second if necessary.

At a meeting of the Royal Geographical Society, held last evening at the University of London, I had the opportunity of hearing some statements respecting health in the Congo region from recent explorers in that district. A few lines may perhaps interest your readers. The seacoast of the Congo region is, it appears, fairly healthy, and Europeans may with safety live much the same as in Europe. The Upper Congo is even more healthy, and few have fallen victims to tropical diseases. The intermediate region is the most deadly, viz., that between the coast and Stanley Pool. In this division about two hundred Europeans are at present living, viz., missionaries, merchants, and others. Of these about fifty have succumbed to the climate. The opinion was freely expressed at the meeting last evening that this heavy mortality was largely due to the privations endured. This view is corroborated by the fact that among mission workers the death-rate has been even higher. The reader of the paper last evening at the "Geographical" (the Rev. T. J. Comber, Medical Missionary to the Baptist Missionary Society) has told me that one-half of those sent by his own Society have died. He also regards the exceptional mortality of the intermediate or "cataractous" region of the Congo as in a great measure due to the hardships which have to be gone through. I may add that medical aid is greatly needed, as I have already mentioned.

While on this subject, I would briefly mention one of our profession, who has lately died on the banks of the Congo. Dr. Sidney Comber is a loss not only to the the Missionary Society whose representative he was, but to the medical profession. Educated for commerce, he determined in early manhood to follow his brother in mission work, and resolved before doing so to become a fully qualified medical man. He had many difficulties in his path, but he succeeded in going to Edinburgh and obtaining his degree with credit amid the most adverse circumstances. Although quite a young man, he gave great promise.

While at Edinburgh he invented a most useful light portable boat, made of wood and canvas, which has since proved very useful in Africa. It may be described as a modification of the "Berthon" boat—only the latter is clumsy in comparison. As one who knew his worth and his many scientific and other attainments, I may be permitted to give this scanty tribute to his memory, and would add, in conclusion, that for several items in some of my previous letters I have been indebted to his accurate memory and ready friendship.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE EPIDEMIC OF TYPHOID FEVER AND CHOLERA AS IT PREVAILED IN PARIS—INSUFFICIENT WATER SUPPLY—INFLUENCE OF THE ANTISEPTIC METHOD IN PREVENTING THE SPREAD OF ERYSIPELAS.

Paris, April 8, 1885.

M. Durand-Clave, a civil engineer and a well-known hygienist, who was lately awarded a prize by the Paris Academy of Sciences, for his work on the "Epidemic of

Typhoid Fever in 1882," presented a series of very interesting charts at the last meeting of the Academy of Medicine on the epidemic of typhoid fever and of cholera which prevailed in Paris during the last few years. The charts are colored and marked with carved lines which show the degrees of intensity of each epidemic in each quarter of Paris, the influence of the winds, of the temperature, of the rain, and of the drinking-water, as elements in the etiology of these affections. The conclusions of the author may be summarized as follows: The epidemic of cholera which reigned at Paris in 1884 caused less than half the number of deaths than that determined by typhoid fever during the same period. There has always been a great irregularity in the distribution of deaths caused by these same epidemics in different quarters of this city. It is, however, worthy of remark that the quarters which were the most seriously affected by typhoid fever, were precisely those which suffered most from the cholera. As these quarters are the most insalubrious of the capital, it may be inferred that the same general causes of insalubrity have an action equally disastrous on the development of the two epidemics in question. Among the circumstances which appeared to have had a certain influence on the outbreak, and on the course of these epidemics, it may be mentioned that the typhoid fever succeeded heavy falls of rain, coinciding with a high atmospheric temperature. The epidemic reached its maximum at the moment when the rainy season had ceased, the temperature still remaining high.

The appearance of cholera coincided with the strong southerly winds, which determined an exceptional increase of temperature, particularly if the month in which the outbreak took place be considered, that is, the month of November. The cessation of the epidemic coincided with the appearance of the strong northerly winds. The density of the population of the quarters affected does not appear to have had a great influence on the appearance of the epidemic, as the latter raged in the poorer quarters, where the houses are more scattered and the population less numerous. Matters are different when houses are crowded with occupants. The mortality was much greater in thickly populated houses than in those less so. As regards the water of Paris, M. Durand-Claye states that it is not the general supply that is deficient; there is water enough, but it is the quantity that is distributed to the houses that is insufficient. The fault, then, rests with the proprietors, who are unwilling to go to the expense. As to the quality, the water of Paris is not so bad as it is generally represented to be. There is, however, one exception, viz., the water supplied from the Ourcq canal, which is notoriously of a bad quality on account of the number of bargemen (fifteen hundred), who dwell on it. Moreover, the canal is a thoroughfare for the boats which convey the filth of Paris to the forest of Bondy, which is a short distance from the town. The statistics show that the mortality from typhoid fever and from cholera was proportional to the quantity of the canal water consumed by the inhabitants of that quarter. In each quarter the mortality appears to have been less where the sewers were in greater number. Finally, it was also less in the quarters where the privies were provided with movable tubs, which are, consequently, more frequently cleared out than cesspools. If the mortality from cholera at Paris be compared with that of the larger cities, where the disease prevailed, the following was the proportion established: At Toulon, the mortality was 75.0 per 1,000; at Marseilles, it was 18.0 per 1,000; at Naples, it was 100.0 per 1,000. As for Paris, the mortality was insignificant in proportion to that of the other towns. I may here observe that in the annual report just issued from the Office of the Prefecture of the Seine, the number of deaths from cholera at Paris, from the commencement of the epidemic in November last, to the end of December, 1884, was 986, of whom 600 were treated in the hospitals. M. Durand-Claye, not being a medical man, did not wish to express an opinion as to the etiological value of the statements he brought forward in his paper, but he submitted the latter as a simple document to be consulted by more competent authorities.

The debate opened by Professor Verneuil, at the Academy of Medicine, and which was referred to in my last—on the influence of the antiseptic method in preventing the spread of erysipelas—was resumed at the following meeting, when Dr. Le Fort declared that the diminution of erysipelas in the hospital wards was due not so much to the so-called Listerism as to the improved methods of treating traumatism, medically as well as surgically. He found that all the methods were good provided they were intelligently carried out and fulfilled certain indications, such as the prevention of the irritation of wounds, the stagnation of pus, and the avoidance of frequent examinations, particularly of wounds of the head, which are so frequently followed by erysipelas, as are also those made by the knife in comparison with those produced by caustics or the thermo-cautery. And this is the reason why the dressings according to Lister, the open antiseptic dressing by Verneuil, the alcoholic by Gosselin, and the cotton-wool dressing by Alphonse Guérin, have all produced more or less favorable results, as they all responded to the same indications. These principles Dr. Le Fort himself carried out without adhering to any particular method, and for the last seventeen years that he has been hospital surgeon he has had only seventeen deaths from erysipelas, five of which occurred during a rather severe epidemic of that affection. Dr. Le Fort, however, admits that the antiseptic method of Lister may, if carried out strictly according to the principles laid down by that eminent surgeon, contribute in a great measure to diminish the number of cases of erysipelas, and to exterminate pyæmia and septicæmia from the surgical and obstetrical wards of the hospitals.

OUR VIENNA LETTER.

(From our Special Correspondent.)

THE TREATMENT OF FUNCTIONAL IMPOTENCE—ON ŒSOPHAGOTOMY—INTERNAL EXAMINATION OF THE ABDOMINAL ORGANS IN THE LIVING SUBJECT.

VIENNA, March 22, 1885.

FUNCTIONAL impotence in the male (*potentia coëundi*) is a subject which Dr. Ultzman has lectured upon in the last semester in a most thorough and exhaustive manner. Every physician in his ordinary practice is constantly having under his charge cases of this affection, and must quite often confess his inability to obtain satisfactory results after long and careful treatment.

Dr. Ultzman divides impotence in the male into four general classes: 1. Organic, a variety which comes rarely to the general practitioner for treatment. Here the trouble is due to a malformation or deformity of the genital organ or the surrounding parts, and these cases are properly referred to the specialist. 2. Paralytic impotence, usually one of the symptoms of a general paralytic affection, and the treatment being that of the primary trouble. 3, 4. Psychical impotence, and impotence due to too early ejaculation of the seminal fluid. These are the two forms which present themselves most frequently, and also the two which yield most readily to the proper treatment. They occur usually in strong, healthy young men who are otherwise in normal health.

According to Dr. Ultzman internal remedies, with the exception of iron and quinine, which are used as tonics in the less common class of cases where the patients are not in good health, are completely useless and do more harm than good. The treatment should be always principally local. The disturbance is a functional one, and consists in the incapability of having a normal erection. Since the capacity of exciting erections resides in the prostate this is the point to which the therapy is to be directed. This is of several varieties; the simplest of all is the sound treatment.

The Charière sounds, beginning with No. 20 French, and continued up to No. 30 French, are introduced daily into the bladder, the patient being in the horizontal position, that being the only proper position in passing urethral instruments. At each insertion the sound is left in from five to ten minutes. It is found to be of benefit after the sound is in the bladder to slightly depress the handle in order to increase the pressure and distention in the prostatic urethra. By this method the metallic pressure alone acts upon the prostate, and usually in a few days powerful erections are excited. In some cases even after a few minutes, while the sound is still in the urethra, normal erections have taken place.

Another method of treatment is with the use of the cool sound (Kühlensonde), the psychrophor. This is a thick metal catheter, closed at the vesical end and divided into two compartments by a partition running the length of the catheter. These two compartments open into each other at the vesical end. At the upper end they form two separate tubes, to which are attached rubber tubes, one carrying the water to the catheter down one side and back the other, and to an empty vessel by means of the second rubber tube, thus having a continuous flow through the catheter, the water coming from a vessel at a slightly higher level than the patient. In this case both the pressure of the catheter, or rather double tubular sound, and the temperature of the water act at the same time upon the prostate. The sound is passed as before until it is into the bladder, daily, but left in a somewhat longer time.

The temperature of the water is usually from 9° to 10° R. Some patients have a urethra which will not bear this temperature; in that case it can be raised 14° to 16° R. In some cases warm water is of value. It is especially to be tried where no result is observed from the use of cold.

Water of a temperature of 30° R., or above, can be used. This, in some cases, has effected a very rapid cure. The thermometric excitation of the prostatic urethra by means of the cool sound, Dr. Ultzman has found of remarkable service.

The use of astringents upon the prostatic portion is a third method of treatment. Small suppositories are carried in, and applied exactly at this location by means of the *porte remède*. Tannin is commonly used and is a good remedy. For the first applications .05, later .10, in a two centimetre long suppository is applied. Urine is not to be passed for half an hour after the insertion. These are to be inserted every day, and continued not less than once in two days until normal erections are excited.

Still another method consists in dropping three or four drops of a five per cent. solution of sil. nit., by means of the deep urethral dropper-syringe of Ultzman, upon the prostatic urethra. This remedy is applied once in three or four days. In impotence, with premature ejaculation, the above remedies are of special value as auxiliary means to the usual treatment of quinine, iron, cold baths, change of climate, etc.

In the paralytic form the above means are always to be tried with faradization. In the use of electricity, one pole is to be inserted into the rectum, the other placed along the raphe of the perineum. The prognosis is, however, very unfavorable.

Two interesting operations for foreign bodies in the œsophagus and stomach were recently made in the clinic of Professor Billroth. The first case was a patient of forty years of age, who, four days before, had swallowed her false teeth with plate. Attempts to get it out immediately after the accident failed. It could be easily felt with a bougie, but in trying to release it the instrument itself was so firmly caught that only after a half hour's work was this released. The patient had a gangrenous odor in the breath, and a painful swelling on the left side of the neck just above the clavicle. Œsophagotomy was immediately performed, and the plate removed with some slight difficulty. The opening, about two inches long, was not closed, and a drainage-tube of about half an inch calibre was introduced through the wound into the stomach, and left there. The wound was then packed with iodoform gauze and a layer of the gauze over it—the patient being fed, of course, through the tube. The tube and gauze were left undisturbed for eight days and then removed. The wound closed by granulation without a bad symptom. At present, three weeks after the operation, no signs of stricture can be made out with a bougie, and the patient was discharged cured.

A few days after this patient entered the hospital, a second almost similar case presented. A girl, nineteen years of age, swallowed in her sleep her false teeth with plate. She immediately made strong attempts to swallow, and the foreign body was carried down to the cardiac orifice of the stomach. Endeavors to get it out not succeeding, she came to the clinic. A bougie could be passed now directly into the stomach without meeting any obstruction. Professor Billroth said that bodies of this size and shape could with difficulty pass the cardiac orifice, but he knew of no case where they had passed the pylorus. The patient complained of a slight tenderness on pressure in the gastric region, otherwise she had no pain. Nothing was felt by the bougie or by external examination. The assertions of the patient were quite positive, however, and Professor Billroth decided to open the stomach. He made a cut, two fingers' breadth, below the edge of the ribs and to the left of the median line, about an inch long, and tried with forceps to grasp and extract the body, but none could be found. The cut was enlarged, and the stomach-wall drawn well forward and out of the opening, but nothing was found. Turning to the audience, Professor Billroth said he had never before had such an opportunity to examine thoroughly the abdominal organs in the living being, and the temptation to do so was too strong to be resisted. The cut was then still more enlarged and he then introduced his hand and part of the arm into the abdominal cavity, talking about the organs as he examined them. He said it was surprising how very soft the liver felt, it was hardly to be distinguished from the intestines. The gall-bladder was well distended. The kidneys were both remarkably movable; slight pressure pushed them downward at least an inch. The bladder was tensely distended. The uterus and both ovaries felt hard and firm. The foreign body was not found. He now introduced his hand into the stomach, and in the upper and backward part grasped and removed the false teeth-plate. The examination was slightly difficult, because of traction caused by the ligamentum gastro-linelis. The wound was then completely closed up with silk stitches and dressed with iodoform gauze. Professor Billroth said that he had discovered what he had not before known, that in drawing the stomach forward and out the portion attached to the diaphragm prevents its being entirely brought forward, and forms a pocket which completely conceals anything lying in it.

About two weeks later the patient was reported in good condition, the wound had closed up as usual when the dressing was first removed after eight days, and she was convalescent. The examination, Professor Billroth stated, had not been in the least injurious to her.

Granular Effervescent Tea.—Dr. Samuel W. Francis suggests that some responsible firm manufacture a superior quality of granular effervescent tea, to be sold by the trade in small twenty-five cent bottles, and in larger ones for one dollar. This would enable persons who are feeble, or tired, or cold, to put one teaspoonful in a tumbler or cup of hot or cold water, and, in a few seconds, enjoy the comfort of a refreshing cup of tea, which is all ready-made, as it could be mixed with milk, sugar, or its equivalent. For those who travel it would prove of great value and become very popular. A handsome income is open to any enterprising company.

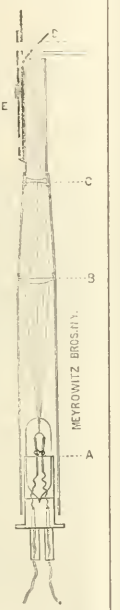
New Instruments.

AN ELECTRIC OPHTHALMOSCOPE.

By WILLIAM T. DENNETT, M.D.,

NEW YORK.

I HAVE had in use for several days an ophthalmoscope which has worked so satisfactorily that I feel justified in bringing it before the profession. It differs from the universally adopted "Loring," in having a much smaller mirror fixed in the usual place and turned at an angle of forty-five degrees, so as to reflect the light from a very small incandescent electric lamp which is concealed in the handle.



A, electric light; B, convex lens of a one-inch focus; C, convex lens of a half-inch focus; D, plane mirror; E, lens-bearing disk.

Every one who is in the habit of using an ophthalmoscope occasionally will appreciate the convenience of such an arrangement when attention is called to the fact that the principal obstacle to the successful exploration of the interior of the eye is due to the difficulty of co-ordinating the various movements of observed and observer in such a manner that the latter may come within seeing distance of the fundus without cutting off the light and so interfering entirely with the examination.

Students always, and experts often, expend more time and trouble in managing the illumination than in all the rest of the process, and an instrument so arranged as to carry its own light to whatever part it is directed, irrespective of the relative position and necessary adjustment of gas, mirror, lens, and other external objects, is certainly a desideratum.

The mirror used in this instrument was less than five millimetres in diameter. The light was about three-quarters of a candle; and light and mirror were ten centimetres apart and in the conjugate foci of a condensing lens about one centimetre in diameter. A few cells of most any constant current battery can be used. The battery which I had could be carried about in the pocket, and was loaned me for the purpose by Mr. Meyrowitz, of Messrs. Meyrowitz Brothers, opticians, to whom I am indebted also for the lamp, and for materials and suggestions of use in construction of the instrument.

Above is a cut of that at present in process of manufacture, it differs from that above described only in the addition of the half-inch lens so arranged that the rays of light are rendered parallel before falling upon the mirror.

105 WEST FORTY-SECOND STREET, NEW YORK.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 19, 1885, to April 25, 1885.

MCPARLIN, T. A., Lieutenant-Colonel and Assistant Medical Purveyor. Sick leave extended three months, on surgeon's certificate of disability. S. O. 88, A. G. O., April 17, 1885.

SMITH, JOSEPH R., Lieutenant-Colonel and Surgeon. Detailed to represent Medical Department of the Army at Annual Meeting of American Medical Association, to be held at New Orleans, La., April 28, 1885. S. O. 91, A. G. O., April 21, 1885.

BILLINGS, JOHN S., Major and Surgeon. Detailed to represent Medical Department of the Army at Annual Meeting of American Medical Association, to be held at New Orleans, La., April 28, 1885. S. O. 91, A. G. O., April 21, 1885.

MCELDERRY, HENRY, Major and Surgeon. Detailed to represent Medical Department of the Army at Annual Meeting of American Medical Association, to be held at New Orleans, La., April 28, 1885. S. O. 91, A. G. O., April 21, 1885.

CRAMPTON, L. W., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Bridger, Wyo. Ter. S. O. 33, Department of the Platte, April 22, 1885.

BORDEN, WILLIAM C., First Lieutenant and Assistant Surgeon. Ordered for duty at Fort Douglas, Utah Ter. S. O. 33, Department of the Platte, April 22, 1885.

ROBERTSON, R. L., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 43, Department of Texas, April 16, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 25, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

THE LATE PROFESSOR JAMES L. LITTLE, M.D., NEW YORK.—*Whereas*, The Northwestern Medical and Surgical Society has since its last meeting lost by death one of its most valued members, James Lawrence Little, M.D., formerly President of the Society—a man who was endeared to every member by his upright character, personal amiability, professional acquirements, and genial manners; therefore be it

Resolved, That in the death of Dr. Little this Society deplores the loss of a most honored and valued colleague—one who by his experience and knowledge contributed largely to the interest of every meeting, and enriched each reunion by his sound sense and practical views.

Resolved, That in our intimate relations with him we learned to respect the able surgeon, the patriotic citizen, the devoted husband, father and friend, the good and charitable physician, and the honest man; striving steadily, perseveringly, and successfully to elevate himself and all coming under his influence unto a higher and nobler sphere of thought and action.

Resolved, That while deeply deploring our own loss we offer our sincerest sympathy and condolence to Mrs. Little and her family; and in thus recording our love and regard for the departed—divide with them the sorrow for his too early demise.

Resolved, That an authenticated copy of these resolutions be sent to the bereaved widow and family, and to THE (New York) MEDICAL RECORD and New York *Medical Journal*, and that they be entered upon the minutes.

MARK BLUMENTHAL,
ED. A. HARWOOD,
EDWIN F. WARD,
Committee.

THOS. H. BURCHARD, *President.*
J. HENRY FRUITNIGHT, *Secretary.*

What is the Cause of Pain in the Shoulder?—Dr. A. H. Smith, of this city, writes: "Mrs. B——, aged about thirty-five, a large, fleshy woman with good muscular development, suffered some twenty years ago, for a year or more, with swelling and severe pain at the top of the right shoulder-blade. The arm was almost useless, any movement which was communicated to the scapula causing intense suffering. The only position in which she was measurably free from pain was with the hand behind the back, and the elbow flexed at a right angle. After a year or more, during which many remedies were employed without benefit, the swelling and pain gradually disappeared, and the movements of the scapula became as free as ever. But there remained, and is still present, a singular condition at the upper and inner angle of the scapula, at which point a loud crunching sound is developed whenever the blade is made to move upon the wall of the thorax. This sound is loud enough to be heard at a distance of two or three feet, and gives the idea of friction between large, rough, bony surfaces firmly pressed together. A crunching vibration is also perceived by the touch. The condition is not accompanied by pain or other unpleasant sensation. The contour of the shoulder is not different from that of the other, nor is the freedom of motion in the least impaired. It is an interesting question what is the condition of the parts which gives rise to this symptom. Under the name of "Scapularkrachen," Albert gives a description of a rubbing sound which he attributes to contact of the scapula with the ribs, brought about by atrophy of the intervening muscles, and which occurs especially in cases of narrowing of the thorax after pleuritis ("Lehrbuch der Chirurgie," Bd. ii., p. 276). But in this case the general muscular development is remarkably perfect, and there is no flattening of the shoulder or impaired action of the arm, such as would result from muscular atrophy. The most probable explanation seems to be that there is a projection, probably in the form of an exostosis, either from one of the ribs or from the under surface of the scapula, which has worked its way through the muscles and affords a point of osseous contact, or that an enchondroma exists in the muscular structure. It is a fact that may have some significance as pointing to a constitutional cause that a pain has lately developed at the lower angle of the left scapula, which resembles in character the pain felt on the right side twenty years ago, and that a son of the patient has an enchondroma springing from one of the costal cartilages."

The "New and Simple Expedient" for the Treatment of Strangulated Hernia.—Dr. A. J. Rosenberry, of Peshtigo, Wis., writes: "I wish to say that I have treated two cases of strangulated hernia by the 'simple expedient,' first mentioned by Dr. C. A. Stewart, of Chicago, and again referred to by Dr. S. H. Hurd in the issue of March 21st, page 319. My experience coincides with that of Dr. Hurd, that much more force than 'gentle pressure' is required to rupture the constriction; in fact, I exerted all the power of my index finger before the resisting structures yielded. The result in both cases was eminently satisfactory, the hernia being at once easily reduced. These cases occurred before the publication of Dr. Stewart's article. The method is that of Dr. Suetin, of Brussels, and is described on page 526, vol. ii., Gross' Surgery Edition of 1882, which, of course, settles the question of priority of discovery raised by Dr. Hurd."

In the Treatment of Amenorrhœa, I should like to call attention to an old but very much neglected remedy. I refer to the common smartweed or water-pepper, botanically termed polygonum hydropiper. Many years ago Eberle, in his work on "Materia Medica," pronounced it the most certain of all emmenagogues, but for some reason or other it is at present very seldom employed. This remedy has a special affinity for the female reproductive organs. I base this assertion on two facts: 1. It restores suppressed menstruation without producing any disturbance or alteration of the general system. 2. It acts as a decided tonic in cases of chronic disease of the uterus and ovaries and relieves many of the subjective sensations due to these disorders. The special virtue of smartweed in chronic uterine disease was discovered for me by a patient who had been suffering from suppressed menstruation in connection with many other symptoms due to a diseased uterus. After the menses were restored, this lady continued the extract of smartweed for several months without my knowledge, but with a very favorable effect. The best and most convenient preparation of smartweed is the fluid extract. This may be given in the dose of a teaspoonful three or four times daily, commencing its use a week before the time for the return of the following period.—*J. K. Shirk.*

Comment and Epigram.—"Nervous exhaustion vaccinates the system against febrile and inflammatory diseases." "Disease itself is the most powerful of doctors." "Syphilis is undoubtedly growing milder with civilization." "What patients confidently expect to happen will be very likely to happen." "'Every man is a rascal as soon as he is sick'—so Dr. Johnson remarks." "Sick headache, some suppose, is related to epilepsy; but experience shows that it saves from epilepsy, just as it saves us from many other diseases; it is a safety-valve through which, if confined, might result epilepsy, paralysis, insanity, or some other disease more fatal, if not more distressing, than sick headache itself." "Lithæmia or uricæmia, like the terms phosphuria or oxaluria, express incidents rather than causes."—*Beard.*

Rapid Dilatation of Cervical Canal with the Urethral Sounds.—Dr. J. K. Shirk, of Lancaster, Pa., finds that the cervical canal can be dilated by means of ordinary conical steel bougies, such as are used in treating diseases of the male urethra. "One would naturally think," he says, "that the sharp curve of these instruments would be a great hindrance to their introduction into the womb; but practically this is of very little moment, since the finger in the vagina can easily change the position of the womb so as to adapt it to the curve of the instrument."

A Remedy for Endocervicitis.—Dr. J. K. Shirk writes in *The Practitioner*: "There is one condition of the cervix uteri which resists all ordinary methods of treatment. I refer to that obstinate form of endocervicitis, in which a discharge quite similar to the white of an egg is poured out in great quantities. In all forms of cervical catarrh this secretion is produced more or less, but in the form I refer to the glands are remarkably active and produce immense quantities of this discharge. As said before, the ordinary forms of astringent and caustic applications will not cure this condition. I have found but one remedy that will cure these cases, namely, an aqueous solution of chromic acid (℥j. to aqua ℥j.). Four or five applications of this remedy at intervals of a week usually suffice." Another mode of treatment is to curette the glands.

Warning against an Impostor.—A correspondent writes: "A man, about thirty-five years of age, of Jewish type, rather good-looking, with short black hair, high-colored cheeks, of slender build, the left first incisor missing in the upper jaw, shabbily clad, visits physicians and proposes to sell them instruments or books, or find good purchasers for books they want to dispose of. In this way he has obtained both books and cash from me, and the addresses of his residence and business place have proved to be fictitious, wherefore I warn others not to allow themselves to be cheated by this dangerous individual."

Stretching the External Nasal Nerve for Glaucoma.—This new operation has been three times performed in this city with good success. Dr. W. O. Moore recently exhibited a case illustrating its efficacy.

THE PHYSICAL EXAMINATION OF WEAK CHESTS AND DIFFERENTIAL DIAGNOSIS OF THE SEVERAL FORMS OF EARLY PHTHISIS.

BY E. DARWIN HUDSON, JR., M.D.,

PROFESSOR OF GENERAL MEDICINE AND DISEASES OF THE CHEST, NEW YORK POLYCLINIC; PHYSICIAN TO BELLEVUE AND ST. ELIZABETH'S HOSPITALS.

OUR system of physical examination of the chest, as developed by Avenbrugger, Laennec, and Piorry, has received numerous emendations and additions from a host of investigators and teachers in Europe and America. The more prominent of those abroad are Skoda, Allison, Gairdner, and Walshe; and not less valuable and original are the contributions, in our own country, of Flint, Loomis, Leaming, Cammann, and Clark.

The profession has come to regard physical diagnosis, in the hands of experts, as affording exact knowledge of the conditions of the intrathoracic organs. It is accepted as a fact fully established that, by the application of acoustic laws, certain combinations of physical signs lead to an immediate and correct diagnosis in most cases of pulmonary disease.

But the interpretation of physical signs can never be dissociated from some theory of the nature of the existing disease, a conception of its pathogenesis, and a knowledge of its gross and minute pathology, as well as of the pathological processes which determine its consecutive steps or stages, and its periods of transition from one to another form.

The conclusions of Piorry in percussion and of Laennec in auscultation were interpreted, therefore, so far as regards pulmonary phthisis, upon the basis of the pathology of Bayle and Louis, the unity of pulmonary phthisis, and the tubercular nature, *ab initio*, of each and every case.

This view of the specific nature of all phthisis, and its transmission solely by heredity, had not been questioned for nearly fifty years.

But the last twenty years have witnessed almost a revolution of opinion as to the prominence, or causative relation, of miliary tubercle in phthisis. It may at least be affirmed that, while division of opinion still exists on this question, a majority of all investigators and of the profession have come to acknowledge the three forms of phthisis—the catarrhal, fibroid, and tubercular—as so clearly presented by Sir Andrew Clark abroad and Professor Loomis in our country.

But there is also reason to believe, not only that pulmonary phthisis presents these three distinct types—the catarrhal or bronchial, the fibroid or interstitial, the tubercular or constitutional—but also that, in very many cases, it exists in a mixed form. A vertical section of many phthisical lungs presents, in irregular distribution, areas of bronchial catarrh, thickened bronchus, peribronchial infiltration, bronchiectasis, interstitial fibroid infiltration, caseation, softening, antrum, and inflammatory changes in the investing pleura, not infrequently extending to the parietal pleura, with intervening intrapleural adhesions. It is not desirable to be diverted from the subject of our consideration, the physical diagnosis, to consider the many unsettled points as to the relative influence of bronchial, interstitial, and pleuritic inflammations in developing this mixed pathological result.

But I am satisfied that in consideration of the different methods of origin, and the complex nature of a large proportion of cases of phthisis, our physical exploration is incomplete if we discover only the presence of cavities and softening, or the evidences of local consolidation. An exact diagnosis should include, *in extenso*, an exact knowledge of the condition of each portion of the respiratory apparatus, including the air-passages, vesicles, interstitial tissue, and pleura.

Under these circumstances it is evident that the chapter on physical examination of the chest, if by any regarded as closed, must be reopened, to admit new facts and new interpretations of the old acoustic laws, in the light of a broader and changing pathological view.

The views which I present relate to the methods of examination most useful in studying weak chests with tendencies to phthisis, in detecting the times of transition from danger to disease, and in differentiating the early forms of phthisis. They include no new theory as to the disease, nor are they the product of speculation, but represent the opinions and convictions which I have reached, first as a faithful student and observer of our several authorities on the subject, and, concurrently, by independent observation in private practice during the past eighteen years, and in my clinics during the past twelve years at the Woman's Medical College, the New York Polyclinic, and my wards in Bellevue Hospital.

I recognize with Simon, of London, that struma or the lymphatic temperament supplies a ready soil for phthisis; with Niemeyer, Rindfleisch, and the Germans of the past twenty years, that the lymphatic capillary tissue of the lungs is essentially the channel of infection for tubercular cases, whether by vitiated air and food, by toxic substances, or absorption of liquefied cheesy products of inflammation. But observation has made me a firm believer in the agency of inflammation as the chief factor in developing pulmonary phthisis, whether in those predisposed by heredity or those free from such predisposition: the latter class I believe to include the great majority of cases. That inflammation, in intercurrent attacks, is the most prominent feature of the progress of phthisis from stage to stage is quite generally recognized.

In our conception of phthisis it will be of advantage to defer the study of the disease in its mixed and complex forms until the essential evidences of the definite types are reviewed. Virchow has exerted a powerful influence in favor of keeping close to anatomical and physiological purposes of parts in the study of their morbid changes, calling attention to the fact that in most organs disease is primarily of its functional structure, or of its interstitial vascularized parenchyma, or of its cortex and investing capsule. It is so with the meninges of the brain and cord, the nerve-substance and connective-tissue. So also in the liver and in the kidneys. Glomerular nephritis, tubular nephritis, and interstitial nephritis start independently, but ultimately become more or less associated in the same organ.

In the thorax, with reference to the respiratory organs, this is especially true. The larger bronchi having a set of afferent and efferent nutritive vessels essentially separate from those of the infundibuli and air-sacs: the latter, while receiving in a limited degree the blood of intervening bronchial arterioles, are possessed of a circulation of their own, the circulation of the parietal pleura being wholly independent of either. We are prepared, therefore, in advance of actual search, to find diseases dis-

tinctly originated in these differently vascularized tissues and regions.

An epitomized statement of the essential physical signs of early phthisis, as generally held, may be included under two heads:

1. That the existence of an area of dulness on percussion, of absent or enfeebled vesicular murmur, with increased conduction and raised pitch of respiratory, voice, and tussal sounds, indicates parenchymatous infiltration, whether of tubercular or inflammatory origin, the air-sacs either collapsed or engorged with catarrhal products—in fact, a consolidation existing which tends ultimately to caseation, softening, and cavity. Local subcrepitus in such an area is regarded as evidence of collateral hyperæmia, or of the existence of a local catarrhal process, tending to further interstitial deposit and further occlusion of air-vesicles. The history of the case influences the diagnosis as to the tubercular or catarrhal nature of the case.

2. That an area of notable dulness or flatness on percussion and of deficient conduction of sounds points to fibroid phthisis. This deficiency of sounds may range from enfeebled sounds, through masked, distant, indefinite sounds, to silence, or, with deficiency of conduction of the breath, voice, and cough, may also be associated diagnostic adventitious sounds, as of emphysema, bronchial constriction, or cavity.

In addition to the above recognized distinction, I believe that many careful students of chest acoustics have come to a recognition of the differentiation of the forms of fibroid consolidation, whether starting from the bronchi, or centric and diffuse, or, again, distinctly of pleural origin. Thus,

a. When over a definite area the percussion note is pronouncedly flat or high-pitched, with relatively but a slight conduction of the normal sounds, unchanged in pitch and quality, and when the sounds, though discernible, are feeble and distant, the fibroid is likely to be peripheral, starting from the pleura, the product of an imperfectly resolved pleuro-pneumonia or of a local plastic pleurisy, leading to underlying hyperæmia and subsequent hyperplastic fibroid.

b. When the union of flatness on percussion and obscuration of respiratory and voice-sounds is pronounced, especially if bilateral and attended with great reduction of respiratory motion on both sides, the fibroid is likely to be more generally and diffusely interstitial. Such is the condition found in advanced cases of gouty diathesis, in brown induration or interstitial results of long-standing cardiac incompetency, and in syphilitic phthisis. The same conditions existing in but one lung cannot be inferred with equal certainty.

c. When the percussion note, relatively, is but slightly raised in pitch, being rather deficient in duration and devoid of pulmonary quality, and there co-exists a general enfeeblement of respiration, a general absence of volume in respiration, the fibroid is likely to have started from the bronchi. The presence of exaggerated tubular quality of inspiratory sound, with slight increase of pitch, of retarded tubular expiration, with or without râles, will further determine whether the case is more specially one of peribronchitis, or bronchial thickening, or bronchial rigidity and dilatation.

The first point which I desire to discuss, with reference to efficient and correct chest exploration, is the importance of examining all parts of the chest. Too often the front of the chest is cursorily examined, with reference chiefly to the condition of the apices. The chest should be divested of clothing, or, in the case of ladies, covered only with a thin merino shirt or dressing sacque, which may be raised in parts as required for inspection of the chest-wall. The chest should be examined from apex to base of lungs—front, side, and back. Two areas, almost wholly passed over by most examiners, often afford most valuable information. These are, first, the high axillary region, and, secondly, the interscapular spaces. The examination in the axillary line high up, with the arm carried over the head, should be made in all cases. It must have come to the notice of very many physicians in private practice, but more often in the grouped cases in general hospitals, that in the course of cases of irregular pleuro-pneumonia, or low and indefinite forms of pneumonia, the product of squalor, dissipation, malaria, or secondary to phthisis, the area of pneumonic consolidation, as evidenced by bronchial breathing, has been found only in the axilla.

The importance of the interscapular exploration is such as to warrant a full consideration. It is here that we have the larger bronchial trunks and the hilus of each lung close to the posterior wall of the thorax. But in the ordinary postures, with the head erect and arms hanging by the side, or even with the arms loosely folded in front, the interscapular spaces are relatively valueless for physical diagnosis. The scapula, on either side, covers the chest from the first to the eighth rib, and comes within an inch of the processes of the vertebræ. This intervening space on each side is filled in by the rhomboideus, minor and major, which span it obliquely from the vertebræ to the scapulæ, and, to complete the muscular envelopment, the trapezius extends from its median origins, at the occiput, the ligamentum nuchæ, the cervical and twelve dorsal vertebræ, in converging bands, over the interscapular space and scapular blade, to its attachment on the spine of the scapula. The value of the upper half of the back for percussion is therefore slight over these thick, flaccid muscles and interposed bony plate. Most physicians recognize this condition, and obviate it, in a measure, by directing the patient to fold the arms. By a forward motion of the arms, the claviculo-scapular union, being essentially fixed, serves as a point of rotation, while the tension of the deltoid on the spine of the scapula directly antagonizes the trapezius and draws the scapula laterally with slight rotation. Dr. Corson, more than any other person, has emphasized the importance of taking advantage of the great mobility of the scapulæ as a means of increasing the interscapular area.

If the arms be crossed in front, each upward at an angle of forty-five degrees, and the hand on either side is made to grasp the convexity of the shoulder, the clavicular attachments and the deltoid so elevate, rotate, and draw outward the scapulæ, that the interscapular space is increased more than twofold, and the previously flaccid and thick muscles are rendered tense and thin, lying firmly on the ribs, and interposing no obstacle to percussion and auscultation of the bronchi, and of the upper inner borders of the lungs. Each interscapular area, before a rectangle of one inch width, extending from the first to the eighth rib, is converted into a trapezoid whose upper truncated apex is fully two inches wide, and whose base is between three and four inches broad. The lower angle of the scapula is elevated to the seventh rib. This great gain in space, however, is not more important than is the advantage from the thinning out of the trapezius and rhomboidei. Finally, if the head be bowed and the neck forcibly incurvated forward, the tension of the levator anguli scapulæ is added; it increases the elevation of the scapulæ by half an inch, and adds to the general tension of the dorsal muscles. The scapulæ have not only been moved laterally, but the thin plates, as located, are firmly held between tense muscles, and interpose a greatly diminished obstruction to conduction of sounds. I would urge the resort to this position as greatly facilitating the study of chronic bronchitis, peribronchial, fibroid, and, indeed, all forms of bronchial and pulmonary disease.

In treatises on the systematic exploration of the chest, "inspection" is, by all authors, placed first; but a variable and limited value is ascribed to it. I am, however, convinced that in a large proportion of chest cases, and in a large number of phthisical ones, an approximate diagnosis can be made by inspection alone.

The second consideration of this paper, therefore, is the diagnostic importance of inspection, and the desirability of extending it, in detail, to all the structures of the thoracic wall. It is customary, with all, to observe certain general features, as the breadth of the shoulders, the equal or unequal volume, the symmetry or asymmetry of the two sides, the relative height of the shoulders, the comparative fulness of respiratory expansion, areas of bulging or retraction, and the relative prominence of the sternum and costo-cartilaginous unions. But three other points, in inspection, of much value, may be briefly discussed.

The first is the direction of the clavicle. Broad shoulders and a nearly horizontal inner half of the clavicle give promise of fully developed lungs. The clavicle in some persons is horizontal in its inner half, though more often it is deflected upward from five to ten degrees, when it curves, going more obliquely upward and backward in its second half, to its scapular attachment. The upward angle of the line of the clavicle, as a whole, is therefore, in healthy chests, within the range of ten to fifteen or twenty degrees. But when the clavicle is deflected upward, and backward, at an angle of thirty, thirty-five, or forty-five degrees, the chest development has manifestly been most defective during a long term of years, and the presumption is in favor of the existence of lungs, undeveloped at their apices, which have never fully occupied the supraclavicular and clavicular areas.

The second point is with reference to the relation which slight lateral curvatures of the spine bear to the condition of the respiratory organs.

An inquiry into the history of a considerable number of cases of lateral curvature will elicit the fact, that its appearance has been subsequent to the occurrence of a pronounced attack of pleuritis or pleuro-pneumonia, or a period of long-continued unilateral thoracic pain with associated cough. It is further found in many of these cases that the deflection is toward the side of the chest possessing most respiratory expansion, and that the concavity of the primary curve, and the convexities of the compensatory curves are toward the side presenting slight or notable diminution of respiratory motion. And further exploration, by means of percussion and auscultation, establishes the fact that the curved section of the spine lies within a zone of the chest, affording evidences of thickened pleura, fibroid phthisis, or peribronchial consolidation. Where this combination of conditions exists, it is reasonable to conclude that the intrathoracic changes of one side, diminish the respiratory action of the overlying muscles, and that an unequal traction on the spine, by the antagonizing muscles of the two sides of the back has resulted in the curvature to the side of greater respiratory action and stronger muscles. I do not mean to imply that any proportion of lateral spinal curvatures are a sequence of pulmonary disease, but to emphasize the fact that this is the case sufficiently often to warrant inspection of the spine in all cases. Barwell has called attention to this fact in so far as it relates to the etiology of the spinal disease. Reversely, it may be noted that pronounced lateral and even angular curvature, originating through dyscrasia or malnutrition, and of long duration, does not materially cripple the contained lungs. From the examination of a considerable number of chests, seriously distorted by spinal disease, I have been surprised to find how generally the lungs and heart have adapted themselves to their changed accommodations. They are often exceptionally healthy, and when otherwise, instead of inflammatory changes or phthisical deposits, we find emphysema alone has been developed as the result of the chest asymmetry.

The third and final consideration which I present, under inspection, as pertaining to early phthisis, is the importance of closely observing and interpreting, with their full significance, the changes in the individual intercostal spaces and also in the supraclavicular space, suprasternal notch, and epigastrium.

A pronounced depression above and below the clavicle, associated with narrow shoulders and marked deviation of the clavicles upward and backward, may exist over feebly developed apices, which, however, are not diseased. But such depression, in a person possessing ordinary breadth of the shoulders, and whose clavicles are but slightly deflected upward, is indicative of consolidation of the apex, whether by tuberculization or inflammatory infiltration. In both cases little respiratory movement will be observed, but percussion and auscultation at once determine which of these two states exists. The sinking in of the infraclavicular space, or of special intercostal spaces, synchronous with the inspirations, and notably in chests which as a whole retain their full expansion, points definitely to the existence of a peripheral fibroid of the lung, originated by plastic pleuritis or pleuro-pneumonia, and suggests adhesion of the opposed pleuræ beneath the points of depression.

When, however, the chest expansion is visibly diminished or suspended, the bony thorax being in a state of fixation, inspiration becomes essentially diaphragmatic. Under these circumstances, sinking of the suprasternal notch, the supra- and infra-clavicular and intercostal spaces, and of the epigastrium, synchronous with inspiration, points to a more diffuse and deeper fibroid, shooting from periphery to centre of the lungs, and drawing not only upon the interspaces of the chest-wall, but also drawing upon the walls of the bronchi, and developing bronchiectasis. Again, resort to percussion and auscultation will verify these conclusions. These fibroid areas and bronchial distortions cannot be dissociated from the study of phthisis; they form a part of it, since they determine the recurring hyperæmia and catarrhal processes, which terminate in inflammatory infiltration and ultimate caseation.

One further phenomenon of the intercostal spaces, of exceptional occurrence, deserves mention. It occasionally happens, in an emaciated chest, that the cardiac impulse, instead of presenting only the usual apex-beat, perceptible in the fifth intercostal space, is equally distinct in the fourth, third, and second intercostal spaces. These interspaces to the left of the sternum are seen to rise and fall, synchronous with the action of the heart. The inference is plain, atrophy and retraction of the thin borders of the left lung, which usually overlaps the heart, have taken place. This condition, as a rule, signifies the existence of advanced phthisis of the lung above and adjacent to the heart; often there is a large antrum and collapsed lung; but I have once found it where fibroid contraction only existed in the adjacent lung. The diagnosis of this condition is confirmed by percussion, since the normally small triangle of superficial cardiac flatness is increased to a large circular or irregular area; and by auscultation, since all respiratory and conduction sounds are wholly removed from this area. I am not prepared to say, from the limited number of cases I have seen, whether this cardiac motion, visible in all four intercostal spaces of the præcordial area, warrants an inference of pleuro-pericardial adhesions. The cases I have seen, have given no history of previous pericarditis, nor of local pleurisy. The retraction of an atrophied, cirrhosed lung establishes direct contiguity of the anterior cardiac surface and the chest-wall. The interposition of pericardial, or even of intrapleural, bands is not essential to the production of this disseminated heart-impulse, and none such are required to transmit the localized normal apex-beat.

Before dismissing the subject of chest inspection, I desire to state my views as to the causative relation of the non-development of the chest-wall and its movements to phthisis. It is well known that the apices of the lungs are the most frequent site of early phthisis. Yet nothing peculiar in the anatomical structure of the apices or in their function explains their greater liability to disease. Women are more prone to phthisis than are men, yet women have a greater development of upper costal respiration or apex expansion than do men. I

believe that phthisis attacks the apices preferably, because:

1. The apices are so frequently enfeebled by contraction of the upper part of the bony thorax, whether by want of muscular activity and development or by rounded shoulders, through carelessness and indolence, or through confining work at desk or trade.

2. That the apex region, in this enfeebled condition, is soonest reached and most easily invaded by the frequent recurring catarrhal inflammations, descending from the larynx and trachea.

3. Because the apices, when invaded by hyperæmia or catarrhal processes, are not favorably affected by the energetic force of cough.

Cough is essentially a diaphragmatic act. It expends its force upon the lower two-thirds of the lungs, tending to clear the lower bronchi of contained mucus, and by compression to remove their hyperæmic conditions. But this benefit is not extended to the bronchi and parenchyma of the apices. It is a fact that in cough, the glottis being in a measure constricted, the forcible currents of air driven upward from the lower portions of the lungs by diaphragmatic force are not permitted to wholly escape through the larynx, but are deflected into the bronchi and vesicles of the upper lobes. When this process continues too long, as in pertussis or chronic cough from any cause, emphysema of the apices or upper lobes (obstructive emphysema) results. In the same manner I believe that cough, by pneumatic pressure, frequently detains or compacts catarrhal products in the tubes and vesicles of the apices, and renders them especially the seat of phthisis.

I shall not dwell on mensuration, since its essential features are established, and it affords but little diagnostic information. Asymmetry of the two sides of the chest, or a marked diminution of respiratory expansion, are to be interpreted by resort to percussion and auscultation.

Palpation as a method of examination, while presenting many special details, is particularly valuable as relates to the subject of fremitus. Fremitus is especially instructive for negative diagnosis, often indicating the normal chest by a vibration communicated to the hands which they cannot misinterpret. But fremitus may be feeble or almost absent in healthy but indifferently developed chests, especially if the voice be treble. It may be weakened by rigidity of the bronchi. Fibroid areas may remove it in whole or in part. Thickened pleura may remove it, or rarely increase it by conduction, depending upon the condition of the bronchi and pulmonary tissues. Finally, the possibility of fremitus under these and all conditions depends largely upon the elasticity of the ribs. When by any cause, whether by senile calcification, or by the inspiratory fixation of emphysema, the ribs are held tense and rigid, fremitus ceases, no matter what the condition of the contained organs. Palpation, therefore, of itself does not afford valuable diagnostic information as to the state of phthisical lungs.

Although most authors and teachers of physical diagnosis recognize the composite nature of the pulmonary percussion sound, and the several factors which unite to produce it, yet the impression prevails that it is essentially the exponent of the underlying lung. It would be undesirable to detract, in the slightest degree, from the diagnostic value of percussion. But its exclusively pulmonary origin is easily disproved. This is most easily accomplished by a brief reference to the percussion note of emphysema. If, in emphysema, the percussion note were to correspond to the volume of air within the coalesced air-vesicles, and in the stretched infundibuli and dilated terminal bronchi, we should obtain, by percussion, the prolonged, low-pitched, tympanitic sound which the novice in physical diagnosis is always prepared to hear. To his surprise the sound, although possessed of some tympanitic quality, is curtailed in duration, and in its initial portion, at least, is raised in pitch. The explanation is simple. The emphysematous lung is an aggregation of fused air-vesicles and distended terminal air-passages; it is a dilated lung, with much of its elastic tissue absorbed, and deprived of its expiratory contractibility. The overlying bony thorax is, therefore, in a state of inspiratory fixation, and so tense or rigid that it does not vibrate. Hence the contact of the percussing finger-tips with a rigid thorax elicits a sound high in pitch and devoid of vibration or duration. I will mention one further fact bearing upon this question. The middle and lower sternal regions overlie the anterior mediastinum, which contains the great vessels, and also cover the body of the heart. Yet, in some elastic chests percussion over the sternum—the keystone of the elastic respiratory arch—elicits, not flatness, but a sound essentially of pulmonary quality. The elasticity of the chest-wall is undoubtedly an essential factor of the percussion-note.

However, it may be affirmed that raised pitch of the percussion-note, especially at the apices, indicates lung condensation—either tubercularization or inflammatory infiltration. It may also mean thickening of the underlying pleura. But when the chest-wall is poorly expanded, whether by disuse and enfeeblement of upper respiratory muscles or when fibroid or bronchial rigidity have transferred respiratory action to the diaphragm, then the motion of the ribs lessens, and the disused ribs become more or less fixed. Under these conditions percussion over the entire chest frequently elicits only an unsatisfactory and negative sound, devoid of diagnostic features.

Reversely, in many cases thickening of the pleura, of recent or remote development, may cause such absolute percussion flatness as to warrant the inference of a solidified, phthisical lung. We may conclude, therefore, that in contracted chests and in the mixed forms of early phthisis, percussion leads to no positive diagnosis, until supplemented by auscultation.

But there is yet another physical sign, or differential test, to which I must call special attention. It may be regarded as a product of mediate percussion. It is in nowise connected with chest acoustics, but rather pertains to the subject of the thoracic innervation and the influence of pulmonary tissue-waste upon the spinal centre. I refer to a special cutaneous reflex which characterizes many, perhaps most, phthisical cases. It is so frequently present at the periods when caseation and secondary inflammations mark a case hitherto uncertain as one of phthisis that it may be regarded as pathognomonic. As early as 1830, in the "Dublin Hospital Reports," vol. v., p. 70, Graves and Stokes described certain muscle tumors which appeared following direct percussion upon the chest "in incipient phthisis, chiefly over the seat of irritation." Dr. Lawson Tait, in 1871, in the *Dublin Journal of Medical Science*, vol. lii., p. 316, described this phenomenon, and designated it more classically as "myoidema." Professor Gairdner and Dr. Finlayson also allude to the diagnostic value of the sign, and properly add that "myoidema" and "muscle tumor" are misnomers, since this reflex is of the skin alone; that it is best produced by a quick stroke of two or more finger-tips upon the costal cartilages, where no underlying muscle exists, and is much less marked over the muscles of the intercostal spaces. I should hesitate to call attention anew to a point advanced so long since by Graves and Stokes, and which presumably had long since passed to oblivion because tried and found devoid of significance, were it not that I have first, and for a long time, carefully studied it upon several hundred chests at Bellevue Hospital and the Polyclinic. Being skeptical of its special relations to phthisis only, I have at the outset asked myself, as most of my students in physical diagnosis have asked me, if it was not present in all cases of emaciation, wasting disease, and slow convalescence. Hence I have sought to find it in the chests of convalescents from protracted and depressing typhoid

in advanced cirrhosis, in abscess of the liver, in hemiplegics and paraplegics, and wherever disease had produced tissue-waste. The result of my observations was: First, that it is usually present in established phthisis, where the long-standing and progressive intrathoracic disease has wasted the body; second, that it frequently exists in incipient phthisis; third, that it is only exceptionally present in any other disease, and its presence justifies a suspicion of phthisis. In but one case, a convalescent typhoid, did it seem pronounced, and so exceptional was this case that, though chest disease was not demonstrable, I felt that its early manifestations might soon appear. Again, in cases of chronic bronchitis, bronchial dilatation, and bronchiectasis it does not appear, nor again in cases of thickened pleura, however extended; but when fibroid is developed, whether of bronchial, interstitial, or pleural origin, so as to contract the chest and to cripple the lungs for respiratory service and lessen the nutrition of the body, it begins to appear. It is most pronounced when elevation of temperature, colliquative sweating, and bodily debility indicate pulmonary tissue-waste and caseation. In advanced cases, with softening, cavity, and excessive muco-purulent sputa, it reaches its maximum. I usually percuss with a quick, firm blow, with two or three finger-tips of the right hand, upon the costal cartilages of either side. Instantly two or three little conoidal tumefactions appear, rising to a variable height in different cases, ranging from one-sixteenth to one-eighth or, rarely, one-fourth of an inch. Remaining fixed for a variable period, rarely so brief as a second, more often two or three seconds, they undergo a subsidence more gradual than the elevation, a vibratile, vacillating, interrupted recession. Finlayson speaks of it as "a peculiar momentary starting and elevation of the skin." Over the intercostal muscles, in some instances, it also can be produced. I have sometimes seen an associated reflex muscle-wave, which floated away toward the shoulder until lost. In some well-pronounced cases of phthisis I have been able to develop myoidema behind in the supra-scapular space, but especially in the interscapular space when broadened by Carson's shoulder position. Myoidema, then, is a cutaneous reflex peculiar to phthisis. "Reflex hyperkinesis," we are told by Ross, "is caused by disease which increases the irritability, and consequently decreases the specific resistance, of the reflex arc in any part of its course," etc. I have therefore, so far as I have studied myoidema, come to regard it as of diagnostic value. I regard it as a corroborative sign of existing phthisis, and as indicating the arrival of a case of phthisis at a point where the nervous system has become weakened, the vitality depressed beyond the point of resistance, and as marking the case as one tending toward an unfavorable result. If found in a case upon which I had hitherto looked hopefully, it would lead me to renew my examination for evidence of infiltration and caseation. I would ask observers of the chest to habitually apply this test and add their contributions as to its value or uselessness. At present I am disposed to regard it as worthy to be added to the associated signs of pulmonary phthisis.

We come finally to the auscultatory evidences of pulmonary phthisis. Enfeeblement of the vesicular murmur and its entire absence have long been regarded as evidences of condensation of lung tissue, even when conduction sounds have not been raised in pitch; and when to absence of vesicular murmur are added bronchial breathing and broncophony no doubt is left of the existence of an underlying area of infiltration. Were all phthisis either *ab initio* or even ultimately, tuberculization, or even disseminated interstitial infiltration, we might need no further combination of physical signs. But every practitioner, and every expert and teacher in auscultation, has frequently been confronted with cases where he found nothing definite, or a most obscure combination of auscultatory signs, rendering the above tests most unsatisfactory. This is explained by the fact that, in mixed phthisis, a combination of peribronchial exudation, of fibroid emanating from the bronchi or the periphery, and of pleural thickening exists to make up the structures upon which the development of the sounds depends, and which are also the media of their conduction. With reference to vesicular murmur, I am not at all sure that the majority of ears can dissociate it during active respiration, on the one hand, from the finer tubular friction sounds, nor, on the other hand, from the sussurus of the thoracic muscles. I am almost certain that the vesicular murmur, or true respiratory murmur, as claimed to be heard during suspended breathing, or the holding of the breath at the height of forced inspiration—the suspension having in view to remove the tubular or friction elements of inspiratory sound—is often confounded with or masked by the muscular sussurus, which is, like respiratory murmur, so characteristically low-pitched, multitudinous, and diffused.

The absence or modification of the vesicular murmur has always, and properly, been regarded as a first warning of phthisis. But the presence or absence, fulness of development, or the enfeeblement of the vesicular murmur, are not of so great value in differentiating the three forms of phthisis, and especially the relative proportion of each in mixed phthisis. The crippling lesions often have so contracted the chest, diminished its expansion, lowered the velocity and force of the incoming inspiratory currents, that but little respiratory sound is developed to be conducted. Under these embarrassments, however, the phonated voice supplies us with a sound produced quite independent of diminished expansion and enfeebled air-currents. And thus, when considerable areas of pulmonary change exist, the voice as it reaches the ear, by its pitch and quality, and degree of dissemination, tells of the media which have transmitted it. Thus the voice is high-pitched, when conducted through tubercular areas, in proportion to the extent and density of consolidation; or it is rendered masked and distant by transmission through moderate thickening of the pleura; it is faint or absent in exceptional cases of very thick pleura, though, *per contra*, in rare instances, a pleura of one-half or three-fourths inch thickness may conduct the voice-sound with raised pitch. But the vibration of the bronchi, the lung parenchyma, and chest-wall by the full voice often gives no indication of the presence of lesser lesions of early phthisis. The pronounced words, especially of a low-pitched voice, are reverberated and resonated in the bronchi unchanged in quality, and are brought to the ear scarcely modified in pitch. Such is the case in slight infiltration, a peribronchial thickening, or limited fibroid; nor will slight thickening of pleura always modify the conducted voice, though its existence may be evidenced by dulness on percussion. In such chests, then, we still need, for conduction, a sound produced independent of the enfeebled chest expansion and slowed air-currents, but more delicate than the voice. This we have in the whisper. I have for a long time come to regard the study of the conducted whisper as of equal or greater value than the study of changed vesicular murmur and conducted voice, and of far wider application in determining and differentiating the early stages of the three forms, and the many mixed cases of phthisis. The patient, directed by the physician, may utter a quiet, almost inaudible, low-pitched whisper, which, in quality and volume, supplies the place of conducted tubular and vesicular sound, and which latter are absent in contracted chests; or he may whisper clearly and audibly; or, again, he may utter a short, abrupt, forcible, high-pitched, aspirated whisper, deficient in volume and duration, but of great intensity, a sound which preserves its characteristics unchanged by slight changes of tissue density, and capable of transmission through bronchial thickening and fibroid areas when the feebler forms of whisper, like the vesicular murmur, would be unconducted and unheard. At the apex, the low pitched whisper, changed by transmission through the pulmonary media to a high pitched sound, is diagnostic of incipient infiltration. The non-

conduction of such a low-pitched whisper—silence only—or the distant transmission of a high-pitched whisper, when associated with transmission of the voice unchanged in quality and pitch, point to peribronchial thickening or centric fibroid of limited extent. But the non-conduction of both the low- and high-pitched whispers, and a distant feeble conduction of the voice, point to a fibroid nearer the surface or progressing inward from a thickened pleura.

Finally, the ear, applied over the chest, often cannot detect differences in small adjacent areas, as in lobular consolidation. By the substitution of the smaller tube of the stethoscope and uttering the incisive, high-pitched whisper, close comparison of adjacent limited areas can be made to great advantage. Chest vibration—an objectionable element, diffusing and disseminating sounds—is excluded, and very direct conduction, by each underlying area, is secured.

I also especially value the whisper tests, for so I have come to regard and call them, in distinguishing a healthy lung from one slightly diseased—a question so often forced upon us by the existence only of failing health and narrowed chest. The low-pitched whisper possesses too little force to vibrate the healthy lung, or, reversely stated, the healthy lung is such a poor conductor of sound, that the ordinary low-pitched whisper sound is dispersed in the aerated lung, and does not reach the chest-wall and ear, or but feebly. As a negative sign, therefore, in examination of weak chests, it is of greatest value, and will rank, as does absence of expiratory sound, as an indication of healthy lung.

The diagnostic significance of conduction of the tubular element of respiratory sound, high-pitched in inspiration, and prolonged and high-pitched in expiration, needs no elucidation. When marked it is diagnostic. But when it is not marked, when, as already stated—by reason of defective chest expansion—no bronchial tubular sound is developed, or it is developed but feebly, the whisper still remains, adaptable for each case and each form of phthisis, and is diagnostic. I have not alluded to the coexistence of cavernous breathing, retarded, blowing, expiratory sounds, the presence of dry or moist râles, and the many other associated signs by which diagnosis is facilitated and confirmed, as I have not aimed to discuss the entire question of chest acoustics as applied to phthisis, but rather the methods which I regard most essential, including methods that are too little discussed and practised. A detailed examination in the light of our present knowledge of the pathology of phthisis, and by the systematic steps of inspection, palpation, percussion, and auscultation, even when supplemented by the family and personal history and the existing symptoms, will, combined, in many cases fail to lead up to final diagnosis. Renewed and patient examinations will be necessary, from time to time, under new circumstances of changing symptoms and pathology. The occurrence of a hæmoptysis is often the occasion of a first examination of a hitherto unsuspected or a long-neglected chest. The physical signs are widely different during the first hours, or the days, succeeding an hæmoptysis. At the time of its occurrence gurgles and râles mark the site of the gravitated blood, or possibly the area from which it escaped. Within a few hours, arrest of hemorrhage and coagulation of the blood may remove these râles. Possibly a local area of muffling of all sounds, with or without dull percussion note, may mark the area of hyperæmia. In twenty-four or forty-eight hours the development of râles may give evidence of a local catarrhal process, or we may find the crepitus of a local pneumonic process. Finally, in some cases no physical signs exist, the hemorrhage having acted to relieve a hyperæmic area.

One further and final point. In the study of incipient phthisis and weak lungs, no more important problem presents, in exploration of the chest, than the interpretation of local areas of subcrepitus, especially if coexistent with dulness on percussion and bronchial breathing, bronchial whisper, and bronchophony. It was one of the errors of the past to interpret subcrepitus, in consumptive lungs, as indicative of the process of softening. We can pretty safely say that there are no auscultatory evidences of softening, except those grosser and manifest sounds, the changeable râles and gurgles associated with forming cavity. Subcrepitus is often associated with softening, but is not in any sense the result of the action of respiratory currents on softening, cheesy matter. Subcrepitus, when local over phthisical areas, if low-pitched and remote from the ear, denotes local capillary bronchitis, or more often hyperæmia and bronchorrhœa—a transudation of serum or sero-mucus into ultimate bronchial tubes. It is, then, a result of obstructed circulation and collateral hyperæmia. If, however, the subcrepitus be high-pitched, brilliant, explosive, and manifestly directly under the ear, it is plainly interpleural. It then denotes that the infiltration of the lung has reached the surface, and given rise to secondary pleurisy, or that the patient from exposure has contracted a local plastic pleuritis.

In all diseases the effort of the physician should be specially directed to arriving at an early and accurate diagnosis. Prognosis and treatment cannot be of value except they be preceded by a correct conception of the pathogenesis of the malady, and the departure from normal conditions which the affected structures have undergone. This proposition is regarded as especially true of systemic diseases, the product of specific infection and sepsis. Yet these diseases often have a period of self-limitation, and progress by stages toward recovery, or are thrown off by an eliminative effort of the system, or can be successfully combated by specific agents, or rendered harmless, until their force is spent, by antipyretics and antiseptics.

But with reference to pulmonary phthisis, it may truly be said that the usefulness of the physician is greatest in the care and restoration of the enfeebled chest, and in the management of chests already invaded by one or other of the wasting processes.

The fully developed consumption is so difficult to combat that it is an *opprobrium medicinæ* that so little can be done. While, then, we are divided as to the pathogenesis—whether phthisis is disseminated through the lungs by the lymphatic capillaries, whether it is of inflammatory origin with subsequent sepsis by softened cheesy matter, or is specifically produced by colonies of bacteria—we may all agree that the suspected and involved areas should early be studied and differentiated.

Bullet-Wounds of the Heart.—Dr. H. L. Harrington, of Monmouth, Ill., writes: "In your issue of April 4th, under the title, 'Is Death Necessarily Instantaneous after Bullet-Wounds of Heart?' you relate a very interesting case. Let me detail another very remarkable case, which came under my observation while House Physician in Cook County Hospital, Chicago, in the year 1875. One evening at dusk, a man, aged about thirty years, was brought in an express wagon, rapidly driven over rough pavements a distance of over a mile, with a bullet-wound of the left side; he was in a condition of profound shock, and was treated accordingly, by means of heat externally applied, stimulants and morphia internally. Reaction ensued, and progressed sufficiently to admit of his moving about in bed, and talking in a loud voice, when he suddenly died, three hours after receiving the wound. An autopsy made by me the next morning revealed the fact that the bullet had perforated the apex of the heart, traversed the entire length of the left ventricle and auricle, and, after passing upward through the right lung, had become imbedded in the right shoulder. The case seems to me to be of enough importance to warrant this intrusion upon your time and space."

"Love thy Neighbor as Thyself," does not apply to the medical man whose patient rings the bell that belongs to another doctor's sign.

THE SEVERAL FRACTURES AND INJURIES OF THE NECK OF THE FEMUR AND THEIR TREATMENT.

By HAL C. WYMAN, M.D.,

PROFESSOR OF PHYSIOLOGY, MICHIGAN COLLEGE OF MEDICINE; SURGEON WEST END DISPENSARY, DETROIT, MICH.

The aim of surgical teaching for the past twenty years has been largely in the direction of refinements in diagnosis. So anxious is the modern practitioner to make a correct diagnosis that he sometimes loses sight of the fact that the methods of examination may be positively harmful to the patient, defeating the object for which he was called, viz., to advise and direct the injured one to the best possible recovery under the circumstances. The indifference and brutality with which American students have become familiar in the German schools, coupled with the zeal for absolute accuracy in diagnosis inspired by German teachers, have been largely to blame for this blot on American surgery.

An American student who had lately graduated in this country, writes me from one of the German medical centres that "he had listened to a very instructive lecture on the drainage of pulmonary abscesses at Professor Blank's clinic, and that the professor percussed his patient's chest as though he intended to knock the abscess out of it." He also wrote, "death closed the scene."

In no class of injuries are the futile and harmful effects of rude and reckless examinations more manifest than the cases of injury to the neck of the femur and the hip-joint of old persons. The old lady slips and falls on the frozen ground or floor, she tries to get up and fails; a doctor is called; he finds her stunned and suffering pain in the back, hip, or thigh. The foot is in normal position, the length of limb what it should be in health. Friends inquire, is the hip broken? is it out of joint? He cannot say; when he gets the patient home he will examine and see. Then he manipulates the limb, flexes thigh on abdomen, rotates the limb outward and inward, and may or may not get crepitus. If he does, she has a fracture. If he does not, she has intracapsular fracture.

The point I desire to submit is this: What good can come to the patient from the determination of a distinction of that kind? Surely none at all. You may say that it makes a great difference in the treatment. So far as treatment based on that distinction is concerned, diagnosis is immaterial. You do best with these cases of suspected fracture when you use no restraining apparatus. Is it strange that the old lady before mentioned should turn out to have an ununited fracture or absorption of the head of the femur after the manipulations her injury was subjected to, then with weeks of confinement in apparatus to restrain the movements of the joint, to have the bedsores, and broken general health? No harm can come to the patient from an examination which consists in a careful interpretation of the impaired mobility and abnormal position of the limb, the length, flexion, extension, abduction, adduction, inversion, eversion, relatively of the injured member to its sound fellow. But beyond this the respecter of good surgery will not go. Take almost any case of ununited fracture of the femoral neck and inquiry will show that the patient submitted to a deal of manipulation for purposes of diagnosis and adjustment of apparatus at or about the time the injury was received. Any case of injury to the same part which has resulted in good union and useful limb, was treated on the let-alone principle, *i.e.*, making the patient as comfortable as possible with the limb in the position where the automatic action of the muscles of thigh and hip places it. My own experience embraces not a few of these injuries, and I can say that I have found cases of suspected and known fracture of the femoral neck to do best when the patient was kept in the sitting posture, the tuberosities of the ischia resting on a hard seat, the feet side by side, and the legs bound loosely together. A hard seat is essential, for a soft cushion permits the tuberosities to sink so that the weight of the trunk and upper extremities is carried on the soft parts of the gluteal region, comprising the sciatic nerves and giving rise to severe pain. Non-union is not a common result of fracture of the surgical or anatomical neck of the femur, no matter what age the patient may be, when this plan of treatment is followed.

RAPID DILATATION OF THE UTERINE CANAL.

By D. TOD GILLIAM, M.D.,

PROFESSOR OF PHYSIOLOGY AND DISEASES OF CHILDREN, STARLING MEDICAL COLLEGE, COLUMBUS, O.

The practice of rapid dilatation of the uterine canal has not yet become sufficiently general to divest it of novelty or to detract from its seeming barbarity. Though its efficiency for the correction of uterine flexion and cervical stenosis is generally acknowledged, the means and methods to be employed are still matters of discussion. So much of crudeness and apparently unwarranted violence attaches to the operation, that the inexperienced shrink from its adoption with instinctive dread. And no wonder, for to him who has seen a violent peritonitis and probably death follow the introduction of the uterine sound; has witnessed the anguish caused by the admission of a few drops of fluid into the uterine cavity; or has had the usual unhappy experience incident to the use of sponge-tents, the practice of rapid dilatation appears at first sight little less than sheer brutality. It is, nevertheless, a hopeful indication that its strongest advocates are found among those who have had the largest experience with it. It is also a significant fact that the use of tents and soft dilators, formerly so much in vogue, has become practically obsolete. This abandonment is the result of a growing conviction of their inefficiency, in so far as dilatation thus effected does not permanently improve the flexion or render the canal more patulous. Then it becomes more and more evident to him who uses the tents that they are not devoid of danger—that, in fact, despite precaution, accidents will happen, so that the practice is embittered by many failures and not a few tragedies.

Thus it is that the more thoughtful and conscientious have been constrained to limit their application more and more, until now, for some time, the use of tents has been practically abandoned.

Having now for some years used rapid dilatation in lieu of tents, I am satisfied that it is much safer and incomparably more efficient. It is more efficient because, as I believe, in rapid dilatation carried to the extent herein recommended, we have a breaking up of the submucous tissues, which forever destroys the integrity of malformed parts and renders impossible that spastic condition so generally found associated therewith, by reason of fretted and overtaxed nerves. Where this is not accomplished, no permanent good is likely to ensue. As illustrative of this fact, instance the patulousness of the cervical canal, immediately following the menstrual effort, even in cases characterized by the most pronounced dysmenorrhœa. Here is dilatation apparently as effectual as need be, and yet the trouble recurs at each succeeding menstruation with invariable certitude. Now, the dilatation effected by tents is similar to that accompanying the menstrual effort, and, barring the chance of inciting to nutritive changes, no more efficient. The tents, moreover, by their long sojourn fret and irritate the tissues beyond all endurance, and by preventing drainage conduce to septic and inflammatory troubles. As in rapid dilatation we seek to lacerate the unnatural bridges and bands of muscular and connective-tissue, which if done without producing a surface breach usually heal kindly and with facility, it follows that a comparatively narrow blade is more efficient than a broader one, and hence the expanding dilator is preferable to the sound.

The means of rapid dilatation resolve themselves into

two classes, *i.e.*, sounds and diverging blades. The sounds are made of hard rubber or steel, and are slightly conical or olive-shaped, and of graduated sizes. These dilate by being forced into the uterine canal one after another consecutively according to size. There is something fascinating in the use of sounds; as the ease of manipulation, the equable expansion at all points, and the beautiful circular enlargement of the canal comport with one's ideas of an ideal dilatation.

In using the sounds the patient may be placed either on the back or in the Sims position. If on the back a Nott's speculum will be found most advantageous. The cervix now being fixed by a strong tenaculum, one of the smaller dilators is introduced. In performing this manœuvre care should be taken to direct its course in conformity to the trend of the canal as previously ascertained by the uterine probe. If there be much difficulty in passing the internal os, the probe may again be introduced, and will then act as a guide to the dilator. In such cases it is always better to place the patient in the Sims position, and use the Sims speculum. To one not accustomed to the use of the Sims method for the purpose in question, the facility of introduction secured by it will be something surprising. The operator must bear in mind that the cervix is very extensible, and under the opposing forces exerted by the tenaculum and the dilator often becomes much elongated. This may prove misleading, inasmuch as he may think that he has passed the internal os, when in reality it has been pushed before the point of the dilator. He will know when he has passed it by the freedom with which the instrument can be advanced into the uterine cavity, the latitude of motion which can be communicated to it, and by its remaining *in situ* when left to itself. If, on the other hand, it has not passed, it will rebound when the pressure is removed. One after another of the graduated dilators is introduced successively, allowing a few minutes' sojourn for each until a degree of dilatation commensurate with the needs of the case has been attained. Unfortunately, as ordinarily made, these dilators do not run above No. 18 American scale for sounds, and are inadequate for permanent good.

A dilatation, in order to be effective and permanent in its good effects, should give a circle of at least one-half to three-fourths of an inch in diameter. Such a dilatation once accomplished will seldom need repetition, and will in most cases permanently relieve the angularity or stenosis upon which may depend the sterility or dysmenorrhœa. For full dilatation the patient should always be thoroughly anæsthetized, and it is a good plan to follow the example of Professor Goodell, by exhibiting a rectal suppository containing a grain of the aq. ext. of opium before beginning. I am becoming more and more convinced that the principle of the use of sounds is faulty, in that the cervix is elongated by counter-forces at the time of dilatation, whereas it should be shortened in proportion to the degree of lateral expansion. Then, again, on account of the circular outline of the sound, submucous malformations are less easily broken than with the expanding blades, and lastly, the repeated introduction and withdrawal of the successive sizes cannot but prove more or less detrimental. Several mishaps, in the form of pelvic peritonitis, long since admonished me to greater circumspection in their use. In the use of expanding dilators I have finally adopted the Ellinger. This has the advantage of a fulcrum support not far removed from the beak, a great degree of expansion, and a parallel action of the blades. This latter I deem of much importance in all cases of extensive dilatation, as there is much less liability to injure the uterine structures than when the blades diverge like those of a pair of scissors. There is, however, something of a tendency of the blades to slip, and unless care be exercised the cervix may be torn by an accident of this kind. The instrument being introduced with the blades closed, in the same manner and with the same precautions described above, the blades are separated by a gradually increasing pressure on the handles. I do not intermit the pressure as advised by some, but push the dilatation steadily and as rapidly as a feeling of safety for the general integrity of the cervix will permit. As a true divulsion is the object in view, there should be no mincing, but a steady, inexorable advance, so that the tissues may be quickly and effectually overawed and subjugated. As a rule the dilatation should be carried to the full capacity of the instrument, which making allowance for the spring of the blades, will be about an inch. Exceptionally one will have to deal with an undeveloped cervix, or one so brittle that he will not feel safe in proceeding so far. In these cases he will content himself with less radical measures, but will usually find that a repetition becomes necessary if he would benefit his patient. After the lapse of some weeks he will not infrequently be gratified to find evidences of development in the hitherto immature cervix, and may now be able to perfect his work. Occasionally several séances will be necessary before full dilatation is accomplished, but these should always be at intervals of several weeks, in order to give time for the completion of the nutritive changes inaugurated thereby.

Since becoming familiar with the use of the Ellinger instrument, I seldom use the sounds except in a supplementary way. When there is difficulty in effecting introduction, one of the smaller sounds will frequently open the way more advantageously than any thing else, and I sometimes follow the Ellinger with one of the larger sounds, which by its uniform pressure at all points conduces to those nutritive changes by which absorption and reposition are effected and the uterine canal finally straightened and enlarged. It has become the fashion among operators to reverse the instrument after full dilatation, so as to make its curve antagonize that of the uterine canal, and thus to bend the womb in the opposite direction. This I seldom resort to, feeling that the risk of injury to the uterine structures by the beak of the instrument more than counterbalances the advantages sought. Dilatation having been accomplished, the dilator is allowed to remain in place for some moments, when, being withdrawn, a solution of bichloride of mercury, one to one thousand, is applied to the canal. I sometimes use iodoform in its stead, which I throw into the cervical canal by means of an insufflator. I never use the uterine plug, from a distrust of its safety and for the reason that a perfect dilatation will in time work its own changes. I am aware that some of our best gynecologists are partial to the use of plugs of glass or hard rubber, grooved or perforated for facilitating drainage, yet as with more thorough dilatation the risk is less, and results equally good, I see no reason to abandon my present practice. The oculist of to-day seldom resorts to the stile for the correction of stenosis of the nasal duct, and we are all aware of how thoroughly certain spastic conditions of the urethra and anus are removed by one thorough dilatation. Is not the same principle applicable to the uterine canal? I may add that for some time past I have dispensed with the vaginal plug in the treatment of vaginismus, and rely entirely on forcible dilatation under ether, followed by a long period of absolute non-interference. My success has been unexceptional. It would be easy to multiply instances illustrative of the principle here involved, but they are sufficient to shield it from the implication of novelty. I have no fixed rule as to the length of time my patients are kept in bed after the operation, being governed entirely by the indications. So long as any tenderness of the pelvic region manifests, I enjoin quietude irrespective of the lapse of time. If much pain or febrile reaction declare at any time, I resort to the use of opium and push it to the extent necessary to abolish all sense of discomfort. This is maintained so long as there is any evidence of inflammatory trouble, and is backed by the use of poultices or fomentations to the hypogastrium. In the use of antiseptics and other means to combat sequences one should be governed by

general principles. In some cases there will not ensue the slightest disturbance, and such patients need not be confined but a few days, but should always be warned to keep comparatively quiet for at least two weeks.

AUTOPHONIA,

BEING AN ABSTRACT FROM THE LECTURES ON OTOLOGY DELIVERED AT THE NEW YORK EYE AND EAR INFIRMARY, BY SAMUEL SEXTON, M.D.

FROM THE NOTES OF ROBERT BARCLAY, M.D.,

ASSISTANT SURGEON.

AUTOPHONIA in this connection refers to the perception by audition of entogenetic vibrations occurring in the head and ears from the performance of the physiological functions of phonation, respiration, circulation, mastication, and deglutition. The phenomena of autophonia were until quite recently believed to depend mainly upon lesions somewhat vaguely referred to the terminal distribution of the auditory nerve in the inner ear. A case occurring in the practice of Dr. Sexton eleven years ago drew his attention to the transmitting mechanism of the ear as the probable seat of disturbance giving rise to such phenomena, and other cases observed a year or two later seemed to confirm this view fully, since slight pathological changes in this mechanism were found to be capable of producing the symptoms of autophonia, tinnitus, etc. Thus by clinical observations in the field of aural disease, rather than on a basis of preconceived physical or physiological theories, should one base the hypothesis that *the phenomena of autophonia are due to a disturbance of the normal equilibrium of tension of the transmitting mechanism of the ear.*

It is well known that vibrations from the vocal cords or from any musical instrument played in contact with any part of the head, as, for example, the cornet or violin, reach the ear by two distinct routes: one being through the circumambient air to the external auditory canal, the other route being through the tissues of the neck and head—muscle, bone, etc.—to the drumhead, the directness of their course depending on the conductivity of the various tissues which intervene. The vibrations of the latter route are not heard in the normal condition of the ear as distinguishable from the former, otherwise interference would result, but, together with vibrations from the circulation of blood or other subjective sources, pass outward unperceived.

In nearly all the diseases of the external or middle ear, and perhaps in some inner ear affections which in any way disturb auditory tension, the phenomena of autophonia are almost invariably met. Two distinct anomalies of the transmitting mechanism, however, most frequently contribute to this, and they may occur in both acute and chronic affections, though most frequently in the latter—they are dislocation of the malleo-incudal joint and alteration in the tension of the membrana tympani, usually due to manometric restoration.

In respect to the former, it is well known that the peculiar construction of the malleo-incudal joint permits of disarticulation in such a way that the transmitting mechanism fails to respond normally to sound-waves arriving through the meatus externus, while those propagated by phonation, respiration, circulation, etc., are now effective upon the incus and stapes irrespective of the malleus and membrana tympani.

Perception of vibrations by tissue conduction varies inversely as that by normal aërial transmission, of the significance of which we may avail ourselves in recommending acoustic devices intended to aid the defective sense of hearing. Thus in totally or partially deaf persons who can hear their own voice, the use of the mouth-trumpet or otacoustic fan may be persisted in for conversational purposes or in instruction.

A knowledge of the modus operandi of sound transmission is of assistance in differential diagnosis of aural diseases; thus the tuning-fork in middle-ear disease is better heard through the tissues proportionately to an increasing defect in aërial transmission, while, even if the perceptive apparatus be alone affected, the tuning-fork is best heard by aërial conduction, if heard at all.

In outward dislocation of the malleo-incudal joint, in consequence of disease, a variable increase of intensity of approaching sound-waves is necessary to effective oscillation, since the membrana tympani must be forced inward far enough to re-establish auditory tension through coaptation of the articular surfaces. Increased impact is likewise required in the relaxed state of the membrana tympani in cicatricial reproduction of the parts.

The thought suggests itself here that it is possible for very intense sound to traverse the membrana tympani secundaria, giving rise to interference of hearing, or even of concussion, as when a horn is blown or a voice is shouted close to the external meatus.

Defectiveness in the transmitting mechanism, as above mentioned, is very often due to the profound changes brought about by the catarrhal inflammation of the tympanum, especially that which accompanies consumption, diabetes, etc. These changes produce characteristic symptoms, which manifest themselves on slight movements, as change in the pose of the head, coughing, blowing the nose, yawning, swallowing, or eructation—all of which acts may alter auditory tension and produce corresponding alteration in the character of audition. This state of the hearing organ is exceedingly distressing, and the patient often experiences alarm quite disproportionate to the actual danger impending. In some instances the interference of subjective sounds prevents perception of external vibratory impressions. Confusion and uncertainty of audition, and consequent mental distress are increased when both ears are differently affected, and a marked phenomenon is double hearing.

Persons in positions requiring the prompt use of their special perceptive functions and voice lose confidence in themselves, not hearing well nor feeling able to converse readily. This is of still more serious moment in those who earn their living as singers, speakers, and performers on certain musical instruments, since, not hearing their own voice or instrument naturally, they are unable to speak, sing, or play correctly, especially in concert. Sometimes the fault is not believed to lie in their own hearing organs, and they fancy that others do not sing or play in tune.

The trouble, however, is not limited to those who can distinguish harmony from discord; indeed, all persons are liable, under similar aural conditions, to discordant sensorial impressions. During the more quiet moments the patient may be annoyed by seemingly unnatural or obtund sounds produced by respiratory or circulatory vibrations. These he likens to sounds with which he is familiar, and, although usually annoying, they are sometimes contemplated with pleasure. The resemblances suggested by the patient's fancy vary according to temperament, musical and acoustical experience and education; thus one may fancy that he hears the music of a band, or a church organ, the "singing" of a tea-kettle, escaping steam, the rumbling of thunder, the voice of a deceased relative, the warble of a bird, the chirrup of a cricket, a distant whistle, the ringing of a bell, bees "a-humming," the roar of a waterfall, or any other familiar continuous sound.

Variations in the degree of auditory tension from time to time produce alternate perception of entogenetic and ectogenetic vibrations, and consequent indecision and error in respect to their subjective or objective nature, a significant fact of which the physician himself should not be unmindful when practising auscultation, since he then closes his own external auditory meatus and must of necessity perceive, at the same moment, subjective vibrations propagated from within his own head as well as the

objective sounds given forth from the patient. The sounds thus heard subjectively, unless recognized and differentiated, will lead to serious confusion and grave errors in diagnosis.

Where nervousness, worry, or mental weakness is associated with such auditory defectiveness, various aural hallucinations are liable to be experienced and may even become veritable delusions, a significant fact to alienists, for our asylums for the insane furnish many cases where the auricle is wounded, a foreign body introduced into the external auditory canal, etc., by patients suffering from aural delusions due to the autophonia of diseases of the ear. It is likewise worthy of note that the marked vertiginous symptoms sometimes associated with autophonia render the descent of stairs or crossing of crowded streets a hazardous undertaking.

Patients with false hearing, who cannot sing in tune, are apt to suspect the vocal organs as the seat of disease, especially if there are present auro-neuroses, such as tickling or fulness in the throat, desire to swallow frequently, or ear-cough. Treatment directed against the throat or nervous system in such cases is, of course, unavailing, and relief can only be obtained by attention to the hearing organ.

The prognosis in autophonia, under proper treatment, is favorable, complete cure being the rule in acute cases, while great relief may be afforded in the more chronic ones.

Clinical Department.

A CASE SHOWING THE ANTIDOTAL EFFECT OF ATROPIA OVER MORPHIA.

Dr. John M. Clarke, of Burlington, Vt., writes: "A man, forty years of age, in good health, took thirty grains sulph. morphine in about four hours. When found he was in a narcotic sleep, with all the symptoms of opium-poisoning. The usual methods of treatment were adopted. Active exercise as possible, cold water to head, strong coffee, etc. Electricity was not given and stomach was not evacuated. I immediately gave by subcutaneous injection $\frac{1}{150}$ grain of sulph. atropia. After half an hour I repeated this dose. Again, in half an hour I gave the same dose and waited the effect. This was all that could be desired. The pupils dilated, articulation returned, and a general improvement began. In five or six hours from the last dose he was comfortable, and went on to recovery, which was completed in about two days."

TREATMENT FOR OXYURIS VERMICULARIS.

A correspondent, "S. S. W.," writes: "If your correspondent who asks for a remedy for *oxyuris vermicularis* will thoroughly and persistently use injections of a solution of boracic acid and borax, say ℥j. of the former, and ℥ij. of the latter, to a pint of hot water (to be cooled to about 110° F. before using), twelve to sixteen ounces of the solution to be thrown into the rectum immediately after the morning stool, and repeated at bedtime, he will probably have success. Each injection should be retained from five to ten minutes, and occasionally it will be necessary to bring the vermin down from the cæcum and upper colon by saline cathartics. Hunyadi water acts well. Santonin and calomel are efficient, but objectionable on account of not always being harmless. The oil of erigeron Canadensis, in five- to ten-drop doses, in glycerine or castor-oil has acted well in some of my cases; but always in conjunction with the injections. I think I have tried all the remedies usually cited, as turpentine, quassia, vinegar, aloes, carbolic acid, salt, iodoform; but in obstinate cases the foregoing has been more efficient than any of them."

Regarding this same subject Dr. F. A. Gordon writes: "I have used with success, the fluid extract cuscura segrada, one-half teaspoonful each night, for some two or three weeks. I prescribed it for constipation, and cured a case of seat-worms of long standing, in a patient sixty-five years of age. I have used the same remedy since in children with success."

Dr. K. F. Purdy, of Elkader, Ia., writes: "Referring to your correspondent who asks for a remedy for seat-worms, I will say that a three-grain suppository of mercurial ointment, repeated every second night until three have been used, will destroy seat-worms root and branch."

A SUCCESSFUL CASE OF TRACHEOTOMY FOR DIPHTHERIA IN A YOUNG CHILD.

As illustrating the good results from early tracheotomy, even in an unpromising case, Dr. H. H. Lee, of West Stewartstown, N. H., sends the following notes:

L. K——, two and one-fourth years of age, previously healthy, was attacked with diphtheria and diarrhœa about November 7th, the tonsils and posterior pharynx being then covered with a false membrane. Breathing was slightly stridulous. Dr. Ward, who first saw the case, gave calomel, ipecac, brandy, and limewater inhalations with concentrated nourishment.

Condition November 8th: Temp., 101°; pulse, 120, feeble; crowing respiration, slight episternal and considerable abdominal retraction during inspiration; hoarse laryngeal cough, no bronchitis; tonsils and post pharynx coated with a thick grayish membrane; profuse diarrhœa accompanied with considerable abdominal pain and distention. Child persistently refused nourishment. No relief from remedies.

We had no tracheotomy tubes, and residing in a "remote country district," could not get one until the following morning. I, however, at once telegraphed for tubes, and, advising continuation of treatment, returned home.

Dr. W. saw patient at 11 P.M. No relief from remedies, stenosis persistent and gradually increasing. Has taken no nourishment and but very little brandy since morning.

At 3 A.M., November 9th, we found the patient decidedly worse; there was marked episternal and abdominal retraction, pulse was becoming quite feeble, and it was only at considerable intervals that she could be induced to take small quantities of diluted brandy from a teaspoon, so great was her preoccupation in struggling for breath, while the peculiar anxious expression of the eye and pallor of the cheek denoted the onset of carbonic oxide poisoning, and the imperativeness of an early operation.

In the morning, as soon as it was sufficiently light, the patient was anæsthetized, chloroform being first used and the effect continued with ether.

The operation was slowly and deliberately performed in the usual way, and was completed with the loss of less than a drachm of blood.

Having no tube to insert, a silver wire was passed through each border of the tracheal wound and the edges separated at first by an assistant, afterward by uniting wires at back of neck, thus making traction on edges of wound.

When the operation was almost completed, just before the trachea was opened, the child was apparently in a moribund condition, no radial pulse, and respiration had ceased; the inrush of air as soon as the trachea was opened excited an expiratory effort, and the patient rallied under hypodermic injections of ether and brandy, artificial respiration, and the application of dry heat.

As soon as the breathing would permit, a flat sponge wrung out of hot water was placed over the tracheal opening, and the child placed under a croup-tent extemporized by lashing an upright to each side of the child's crib and spreading an ordinary flannel blanket over them; into this was directed a current of steam and lime-water spray.

In a short time the patient, who had, since first taken, steadily refused nourishment, would swallow with avidity all the milk, brandy, egg-nog, etc., that was offered it.

The tube came in the morning's mail and was inserted at 2 P.M.

The child was confined to the tent but a few hours, as it was soon found that fresh air moderately laden with steam had a much more beneficial effect. This was secured by leaving a window open at the top, the room being kept at a temperature of about 70° by the heat of an old-fashioned wood fireplace, a steam atomizer furnishing the moisture. Extreme restlessness was allayed by one-sixteenth grain morphine, hypodermically. During the next two days the patient was in a critical condition, but she then rapidly improved and made a good recovery.

HYDROBROMATE OF COCAINE.

Dr. A. B. Lyons, of Detroit, Mich., has succeeded in producing a new salt of cocaine, the hydrobromate, which he predicts will in the future hold the first rank among the compounds of this drug. The two requisites of a salt of cocaine are that it should exist in a crystalline form, and that it should not be readily deliquescent. These requirements are met by the hydrobromate. "It crystallizes in slender prisms of snowy whiteness, which are readily soluble in water, yielding a perfectly colorless solution." The writer thinks, also, that this salt may perhaps possess some trifling advantage over the others, gaining something in sedative power from the bromine entering into its composition. He has, however, as yet had no opportunity to experiment with it clinically in order to determine its especial value in this respect.

THE EFFICACY OF LACTIC ACID IN THE DESTRUCTION OF NEW GROWTHS.

Dr. A. Rose, of this city, writes calling attention to the value of lactic acid in the treatment of caries fungosa, lupus, epithelioma, and other new growths. As stated by von Mosetig-Moorhof, it destroys, when applied in concentrated form, the proliferating neoplasm, while leaving unaffected any little islets of sound tissue that may be present. This preservation of the healthy tissue within the diseased parts gives lactic acid a preeminence over caustics, which destroy both friend and foe alike. The acid has been used with excellent results in cases of epithelioma, which could not be operated upon or which had returned after operation.

PUERPERAL ECLAMPSIA—RECOVERY.

Dr. W. A. Hulse, of Bay Shore, N. Y., relates the following case of puerperal eclampsia successfully treated: Mrs. R——, aged twenty-eight, was found, two months before delivery, to be suffering from general anasarca and some symptoms of uræmic poisoning. The urine was albuminous, and contained granular casts and renal epithelium. She was put upon digitalis and acetate of potash, with relief to most of the symptoms, but albumen was always present. The labor was a difficult one, with strong but ineffectual pains, due partly to the fact that the cervix pointed upward and backward into Douglas' cul-de-sac, so that the pains were spending their force on the anterior wall of the uterus. An attempt was made to rectify the faulty position of the cervix by traction with the middle and index fingers, and was followed almost immediately by a convulsion. Assistance was sent for and arrived at the end of half an hour, after two convulsions had occurred. A hypodermic injection of pilocarpine one-half grain and morphine one-eighth was at once given, and the patient was brought under the influence of chloroform. At the expiration of thirty minutes more the woman was delivered of a girl by means of the forceps. The child was cyanosed and apparently dead, but was revived by artificial respiration. The patient in the meanwhile had two more convulsions, and was in a comatose condition, with stertorous and jerking respiration, and a thready and very rapid pulse. At the end of two hours she could be revived sufficiently to swallow two drops of croton oil, and from that time received ten grains of chloral and twenty grains of bromide of potassium with brandy every four hours. Several hours later the croton oil was repeated, the first dose not having had the desired effect. This was followed by several free watery evacuations, the kidneys acted freely from the pilocarpine, though there was but slight effect upon the skin. The patient had more convulsions and made a good recovery, and now both mother and child are doing well.

COMPLETE COMPOUND DISLOCATION OF THE TIBIA WITH FRACTURE OF THE FIBULA—RECOVERY WITH NEARLY PERFECT USE OF THE JOINT.

Dr. A. D. Binkerd, of Cincinnati, sends us a report of the following interesting and instructive case: A man forty-five years of age, of vigorous health and temperate habits, in jumping from a swiftly going wagon, was caught by the foot between two sticks of timber and fell outward. This violent strain resulted in a transverse fissure of the skin and soft parts across the internal malleolus; the deltoid ligament was torn from its attachments to the tarsal bones, bringing with it fragments from the scaphoid, astragalus, and calcaneum. The fibula was fractured at a point about two and a half inches above its lower extremity, and the foot was everted to a right angle with the axis of the leg, forming a complete luxation, with the internal malleolus protruding through the fissure in the integument, and the synovial sac exposed to the air. Within forty minutes after the accident the patient was seen by Dr. Binkerd. In order to effect a reduction, it was necessary to incise the lower border of the wound, so as to allow the internal malleolus to return. The hand being thoroughly cleansed in warm carbolized water, the interior of the joint was explored with the index finger and found to be free from any foreign body. The osseous fragments were snipped off from the deltoid ligament with the scissors, and the parts were restored as nearly as possible to their normal position. The edges of the T-shaped wound were approximated by several sutures, and a loose starch bandage applied, room being left for the anticipated swelling. This was accomplished in a reasonably short time without the use of an anæsthetic. The patient was now put to bed, pain being controlled by hypodermic injections of morphine. Ample drainage of the wound was provided for, and the parts were kept constantly moistened with lead and opium wash. The condition of the kidneys and bowels was closely watched, and the patient received ten grains of quinine once a day, and tincture of the chloride of iron in full dose after meals. The patient was allowed to partake of a great variety of nutritious food and in as great quantity as could be digested. The temperature scarcely rose above the normal during the entire course of the treatment. No inflammatory action took place within the joint, and the patient did so well that he was allowed to return to his home in the country at the end of eighteen days. Convalescence went on without interruption and without the occurrence of a single untoward symptom. From a letter recently received from the patient, more than seven years after the accident, Dr. Binkerd learns that walking with the aid of a staff was begun about four months after the receipt of the injury. From this time, strength and motion in the joint increased steadily, until now, "while the wounded foot is not as strong as the other, the motion is more than half as great, I may say two-thirds as great, as that of the other foot."

Progress of Medical Science.

Virchow on Croup and Diphtheria.—In a recent address made at the Berlin Medical Society, Professor Virchow restated the views he haslong held upon the pathological dissimilarity of croup and diphtheria. He briefly reminded his hearers that the term croup, originally a clinical phrase expressive of a prominent symptom of acute laryngeal affections, was first applied in a pathological sense by Rokitansky to all pseudo-membranous affections of mucous membranes, and extended by him to visceral inflammations characterized by fibrinous exudation. In 1847, Virchow, in the first volume of his *Archiv*, pointed out the anatomical distinctions between a croupous and a diphtheritic inflammation of mucous membranes, the former being an exudation upon the surface of the membrane, the latter a necrotic process, in which the false membrane is composed of the exfoliated tissue. At that time he knew nothing of micro-organisms in connection with diphtheria, but he had observed masses of granules, as he then supposed of albuminous nature, in the substance of the diphtheritic membrane, which were never present in the croupous exudate. Nor has he ever been enabled to admit that all cases of fibrinous laryngitis and tracheitis are due to diphtherial poisoning, and he had preparations in which there was not the least evidence of diphtheria. His contention was that the diphtheritic process invariably led to destruction of the mucous membrane, and this recognition of an anatomical difference between croup and diphtheria was, he thought, of prime importance in regard to prognosis after tracheotomy, for in the one case the detachment of the false membrane did not, as in the other, leave any ulcerative lesions behind. In support of this he showed preparations of diphtheritic laryngitis and tracheitis with ulceration.—*London Lancet*, March 14, 1885.

The Spleen in Syphilis.—The view advocated by Mr. Jonathan Hutchinson, that syphilis may be regarded as an acute specific fever in which the various stages are much more prolonged than in the ordinary acute specific fevers, is one which cannot fail to keep the mind open to the possibility of the occurrence of those phenomena which are most usually associated with specific fevers. Facts dealing with the occurrence of alterations in the size of the spleen in syphilis are, of course, familiar to all, but the enlargement of the organ in the early stages of acquired syphilis still remains a debatable question in the minds of some clinical observers. Dr. Avanzini contends that the spleen undergoes demonstrable enlargement just prior to or in that stage of syphilis when the skin and mucous membrane are the seat of the ordinary secondary manifestations. He has also observed that after treatment diminution in size of the spleen, sufficient to cause the disappearance of the cutaneous and lymphatic lesions, does not take place.—London *Lancet*, March 21, 1885.

Alcoholic Paralysis.—Of late years the paralysis which results from the abuse of alcohol has been accurately described by numerous observers, and the attempt has been made to discover the lesion of the nervous system which is associated with this form of paralysis. Two cases, which are reported by Dr. Henry Hun, of Albany, in *The American Journal of the Medical Sciences* for April, 1885, are typical examples of this disease, and may contribute to a better understanding of it. Dr. Hun has also collected the recorded cases of alcoholic paralysis, and from their study he holds that we are justified in regarding it as a special form of disease with the following symptoms: After a number of cerebral and gastric disturbances, due to the alcoholic poisoning, the symptoms of the disease proper commence with neuralgic pains and paræsthesiæ in the legs, which gradually extend to the upper extremity, and which are accompanied at first by hyperæsthesia, later by anæsthesia, and in severe cases by retardation of the conduction of pain. Along with these symptoms appears a muscular weakness which steadily increases to an extreme degree of paralysis, and is accompanied by rapid atrophy, and by great sensitiveness of the muscles to pressure and to passive motion. Both the sensory and the motor disturbances are symmetrically distributed, and the paralysis attacks especially the extensor muscles. In addition to these motor and sensory symptoms there is also a decided degree of ataxia. The tendon reflexes are abolished, and vaso-motor symptoms, such as œdema, congestion, etc., are usually present. Symptoms of mental disturbance are always present in the form of loss of memory, and in transient delirium. The lesion is, in all probability, a degeneration of the peripheral nerve-fibres and of the nerve-cells in the cerebral cortex, together with a chronic congestion or inflammation of the pia mater. This lesion explains well the symptoms, although it is certainly curious that alcohol should not attack the spinal cord, but only the highest and lowest part of the nervous system, if one may so call the cortex of the brain and the terminal branches of the peripheral nerves.

Writer's Cramp and its Treatment.—In *The American Journal of the Medical Sciences*, April, 1885, Dr. R. P. Robins, of Philadelphia, records three cases of writer's cramp, and gives a careful clinical study of the disease. As regards treatment he finds absolute rest is essential. If there be atrophy of the muscles, stimulating lotions, with rapid friction, may be employed; and he has seen good results follow alternate douching with hot and cold water. Finally, in electricity we have a most important factor. As regards artificial aids, Dr. Robins recommends that of Von Nussbaum as possessing, to a greater degree than any of those proposed, the advantages of lightness and simplicity. One of Dr. Robin's patients has derived much benefit by alternating with the ordinary penholder a little apparatus which was made of an ordinary solid rubber ball; this was perforated at about one-third of its circumference and a penholder was thrust through. The ball was held in the hand, and the penholder passed up between the first and second fingers.

The Diagnostic Value of the Bacilli of Tuberculosis.—Dr. Müller, of Würzburg, examined the expectoration of fifty-two patients suffering from measles, whooping-cough, croupous and catarrhal pneumonia, pulmonary infarction, heart-disease with pulmonary and bronchial catarrh, etc.; but, though all the preparations were carefully treated by Ehrlich's method, in not one were red-stained bacilli discovered, and their absence was also ascertained after the most searching examination of the sputa in cases of bronchiectasis and fetid bronchitis, in which other micro-organisms of all kinds abound. On the other hand, the examination of the sputa of seventy-two phthisical patients led to their detection in sixty-seven; in a few incipient cases, however, not until after several trials. The five in which they were not observed were of this class, and four of them left the hospital too soon to give any satisfactory result. But in five others the diagnosis, made solely on the strength of the fact that bacilli were present, was subsequently confirmed by the development of physical signs. In striking contrast with these was a case of chronic pneumonia, with wasting fever and consolidation of the apices, in which bacilli were sought for in vain until a few days before death, when they suddenly appeared in considerable numbers. The pneumonically infiltrated apices were found after death thickly studded with gray tubercles, a few of which had recently broken down and become confluent. In several cases, the symptoms of which closely resembled those of phthisis, the continued absence of bacilli led to the diagnosis of bronchiectasis, etc., confirmed by the further course of the disease; while in others the tubercular nature of the affection was early indicated by the appearance of bacilli and verified post

mortem. Müller considers that from a diagnostic point of view the presence of bacilli in the expectoration is of far greater value than that of elastic fibres, since these will be found in any destructive process, tubercular or non-tubercular. In six cases of more or less chronic pleurisy, a tubercular origin was negatived by the absence of bacilli from the expectoration, and absorption was ultimately effected; whereas, of six others in which they were present, in three of these, before any physical signs of tuberculisation could be made out, the unfavorable prognosis was justified by the result. On the other hand, so long as there was no direct communication between the seat of the tubercular process and the serous cavities, the search for bacilli in exudations was invariably fruitless. It was so in nine cases of pleuritic effusion, serous or purulent, though in four of these they were abundant in the expectoration, and in two of peritoneal effusion, in which there was a strong suspicion of tubercle. But they were found in the purulent and in the serous fluid from two cases of pneumothorax, in one of which a minute communication between a pulmonary cavity and the pleural space was detected after death. The second case presented two remarkable features, viz., that in a second sample of the fluid, drawn off three weeks later, only three bacilli were found in sixteen preparations; and that after the establishment of the pneumothorax the scanty expectoration contained notably fewer than before, the patient's general condition being at the same time greatly improved. From these facts, Dr. Müller infers that the pleuritic exudation does not present a favorable medium for the cultivation of the bacilli, and that the compression of the lung-tissue by the pneumothorax checks the activity of the tubercular process. The examination of the fæces in the case of phthisical patients suffering from diarrhœa was not conclusive as regards the diagnosis of intestinal tubercle, since the bacilli might have been swallowed with the sputa; and the same applies, *mutatis mutandis*, to the diagnosis of tubercular laryngitis. Müller failed entirely to detect bacilli in the breath of palpably tubercular patients, whatever method he employed for their arrest. This negative experience agrees with the position maintained by Nägeli, that micro-organisms are not liberated from fluid media, and with the failure of Günther and Harms to infect rabbits by means of the breath of tubercular men or animals. As a general rule, the rapidity of the course of the disease and the intensity of the febrile disturbance are directly proportioned to the number of the bacilli in the expectoration, and this affords an important indication in prognosis. The exceptions to this rule, frequent though they be, are easily explained on anatomical considerations. When in acute febrile cases bacilli are not numerous, it will usually be found that there is extensive gelatinous infiltration, that there has been but a scanty formation of cheesy nodules, and that the cavities are few and small. On the other hand, when the bacilli are out of all proportion to the fever, etc., the probability is that one or more cavities of considerable size communicate freely with the bronchi, and that the secretion is abundant. The inner walls of cavities are the chief seats of the development of the bacilli, whereas in the surrounding inflammatory and infiltrated zone they are few, or even altogether absent. They abound also in the caseous masses and necrosed portions of the lung; but, if these are circumscribed by inflammatory infiltration, their extension is limited and their escape is checked. As regards the size of the bacilli, they are least in minute tubercles of basilar meningitis and of miliary tuberculosis, as well as in the early stages of peribronchial deposit, while in lung-cavities they are found of every size, from the least to the greatest. —*The London Medical Record*, March 15, 1885.

Spontaneous Rupture of the Membranes at Full Term.—Dr. G. W. H. Kemper, of Muncie, Ind., in the April issue of *The American Journal of the Medical Sciences*, offers a study of 50 cases of spontaneous rupture of the membranes, occurring in his first 700 obstetrical cases, and he finds that: 1. The spontaneous rupture of the membranes at full term of gestation, and preceding the beginning of labor-pains, is an event of common occurrence, averaging about once in every fourteen labors. 2. When the membranes are broken, as a rule, labor supervenes at once, or within the next four hours, but may be delayed several hours, days, or even weeks. 3. When such an accident occurs, the duration of the labor is not necessarily prolonged, nor rendered more painful. 4. The mortality of the mothers is not augmented, and the ratio of stillborn children, if at all, is so slightly increased as to amount to a minimum. 5. The causes are not well defined. The repetition of the accident in certain women shows that with some a tendency is inherent. A possibility of atmospheric influences, especially a low temperature, as an exciting cause is admissible. Smellie considered obesity a cause. His observations have not confirmed this statement. 6. It is probable that the duration of labor is shorter in cases where the appearance of pains is delayed for some time after the membranes are ruptured. 7. The proper plan of treatment, as given by Smellie, McClintock, Bard, Denman, and Dewees, and corroborated by Dr. Kemper's experience, is rest, if necessary in a recumbent posture, and patience. All efforts to excite labor-pains are hurtful, meddlesome, and mischievous. Wait for pains, and treat the case on general principles! 8. Finally, that the fear of delay and danger in this class of cases—the classical "dry labor"—promulgated by our early obstetrical fathers, and indorsed by successive authors generally, is based on a merest spark of truth, and is one of those medical traditions that experience shows to be over-estimated and to a large degree apocryphal.

Measurement of Refraction by the Shadow-Test, or Retinoscopy.—In an article in the April number of *The American Journal of the Medical Sciences*, Dr. Edward Jackson, of Philadelphia, traces the history of the shadow-test from its introduction ten years ago, by Cuignet, of Lille, to the present time. He describes the optical basis of the test, and considers its application in the various states of refraction. It may be looked upon as the union and evolution of two modes of examination almost as old as the ophthalmoscope itself, namely, the twirling of the mirror to detect conical cornea, and the examination of the myopic eye by the indirect method without the intervention of an object lens. Its advantages are that it is most widely applicable, has the certainty of an objective method, the accuracy of trials with test-lenses, and the rapidity of the optometer. It is applicable in the cases of young children, the amblyopic and malingerers, in which subjective tests cannot be used; and in cases where restlessness, nystagmus, hazy media, or the loss of the other eye, renders accurate examination in the erect image by a refraction ophthalmoscope, difficult or impossible. In certainty, when the patient retains the power of accommodation, it seems inferior to the "direct method" as a means of discovering and measuring latent hypermetropia. But it is superior to the direct method in the detection and estimation of astigmatism. In accuracy, the test very nearly equals the subjective test with trial lenses for patients who have good vision, good intelligence, and honesty; for patients lacking in any of these requisites for subjective testing, it is markedly more accurate than any other method. In all cases where the state of refraction is to be measured accurately, it effects a saving of time; in the stupid or sluggish this saving is very great.

A New Treatment for Pelvic Hæmatocele.—Dr. L. B. Couch, of Nyack-on-Hudson, believes that he has devised a successful and simple treatment for arresting hemorrhage in pelvic hæmatocele. It consists simply in raising the foot of the bed till the patient lies at an angle of sixty degrees. Dr. Couch reports a case in which hemorrhage ceased, and life was apparently saved by this measure.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, May 9, 1885.

THE INTERNATIONAL MEDICAL CONGRESS AND THE RECENT ACTION OF THE AMERICAN MEDICAL ASSOCIATION.

THE right should prevail, and its prevalence should secure harmony. The truth concerning the relation which exists between these two bodies centres in the power given to the Committee elected by the Association in 1884 to invite the Congress to hold its next meeting in this country in 1887. If that Committee, with whose work the medical profession, not only here but abroad, is now familiar, was empowered by the Association to enlarge its membership and to complete the organization of the Congress, then the so-called additional Committee, elected in 1885 at New Orleans, has no right to an existence or to recognition, and whatever work it may perform must necessarily be of no avail.

If, on the other hand, the Committee elected in 1885 constitutes the only one empowered to complete the organization of the Congress, then that which has been done by the Committee elected in 1884 is of no account, unless it be endorsed as an act of courtesy.

This incongruous state of affairs, however, can be settled very readily. In 1884 the Association elected a Committee of seven, whose duty it should be to invite, in behalf of the American medical profession, the International Medical Congress to hold its meeting in Washington, D. C., in 1887, and the Association further resolved that the Committee should have power to elect its own officers, and, in case the invitation was accepted, to act as an Executive Committee to make all necessary and special arrangements for the meeting. In other words, the Committee was elected with full power to complete the organization of the Congress if the invitation to meet in this country was accepted, and at the time it was created it was clothed with this power because the opinion was unanimous that time was an exceedingly important factor in the immense preliminary work.

The language of the resolution is as follows: "That the Committee shall elect its own officers, and that, in case the invitation is accepted, it shall proceed to act as an executive committee, with full power to fix the time and to make all necessary and special arrangements for the meeting of such Congress, and to solicit funds for this purpose." . . . "That it shall have power to add to its membership, and to perfect its organization, and that to meet the preliminary expenses of printing, postage, etc., the Chairman of this Committee is authorized to draw upon the Treasurer of this Association for an amount not exceeding four hundred dollars."

The original Committee of seven consisted of Austin Flint, of New York, I. Minis Hays, of Pennsylvania, C. Johnson, of Maryland, G. J. Engelman, of Missouri, J. M. Browne, of United States Navy, J. S. Billings, of United States Army, and H. F. Campbell, of Georgia, President-elect, and added by special vote of the Association.

It being true, then, that the committee of invitation was made an executive committee and was clothed with full power by the Association, the organization of the International Medical Congress as it now stands is entirely independent of the American Medical Association, and is *the* body which is to represent the American Medical profession in international Congress assembled in Washington in 1887.

The recent action taken by the American Medical Association is, therefore, no more effective than would be a pope's bull against a comet, and was an untimely and over-zealous effort to undo what had been placed in charge of a committee previously elected to discharge without restriction a special duty. The resolution which created the Committee does not ask it to report, thus showing clearly that it was the intention of the Association to give it full executive power. The work which it has performed should be accepted without special dissent by all who have any interest in the forthcoming meeting of the International Medical Congress, as its success depends upon its remaining undisturbed. The grievances which were presented at New Orleans are too trivial to require serious comment. The sources from which they came, and which coaxed the Association into performing a meaningless act, give no guarantee that the work can be any more satisfactorily performed than it has already been.

But cannot the Association revise the work of a committee which it created? No; when that committee was elected with full executive power. Certainly it cannot elect a second committee to revise the labor of a committee so constructed. The only point at issue is, Did the Association elect the original committee as an executive as well as inviting committee? The language of the resolution is too plain to receive any other interpretation than that it did, and therefore its work should stand.

THE TREATMENT OF CANCER IN THE LAST HUNDRED YEARS.

IN some of the recent numbers of the *Deutsche Medizinal-Zeitung* Dr. H. Helmkampff has contributed a series of articles upon carcinoma and its treatment in the past hundred years. After reviewing the pathology of the subject, he discusses cancer from a surgical standpoint, and shows, what is already well-established, that the knife has done the most for the relief of this disease.

Some facts with regard to medical and dietetic treatment are then given, and they may be briefly summarized here. The use of arsenic internally in cancer is an old one. Recently it has been energetically revived by several Southern physicians. These latter, however, are only doing what has already been carefully tried in Es-

march's clinic at Kiel. After operations, and in cases in which operations are impossible, Fowler's solution is given in increasing doses to the point of tolerance. Esmarch is also in the habit of spreading upon the wound daily a half-teaspoonful of the following solution: ℞. Acid. arsenios., morphiæ muriat., āā gr. iv.; calomel, gr. xxx.; gum arabic, ʒ iij. M. Beneke's diet is strenuously enforced. In the belief that in some cases cancer develops in a syphilitic or scrofulous dyscrasia, iodine and iodoform have been prescribed by Esmarch, Nussbaum, Panthel, and others.

Nedopil reports fifteen cases in which cancer of the tongue developed from psoriasis syphilitica.

The utility of silicum in cancer was put forward by Dr. R. F. Battage, of London, in 1874 (*Edinburgh Medical Journal*, November, 1874), and again in 1880. About ten grains are given morning and evening. The progress of the disease is delayed from two to ten years. Chian turpentine appears to have had its day. It was tried by Macleod, Morris, Tait, and others without good results. Nevertheless, Dr. John Clay, before his death, reiterated his views as to its value in the early stages of cancer.

Professor Luton, of Rheims (*Schmidt's Jahrb.*, No. 2, 1881), obtained good effects from the use of eucalyptus globulus in cancer of the stomach and uterus. He gave two and a half drachms of the tincture for a month.

A drug which has been highly endorsed for its specific properties is guaco, a South American plant, of which tinctures have been prepared by a Parisian pharmacist. Although its utility has been recognized by such men as Ricord and Maisonneuve, of Paris, Heyfelder, Weinberg, Medan, and Arsenieff, of Russia, the drug seems to be little known. Confidence in it was doubtless lost through the researches of Guibourt, who found that the true *Mikania guaco* was inert, and that the drug ordinarily so called was a mixture of uncertain character.

The history of cundurango is quite well known, and there is no credence placed in its anti-carcinomatous powers by the profession in America. Of late, however, several Swiss and Russian physicians have taken it up and claim for it some remedial value.

CHEAP DISINFECTANTS.

We have received a copy of the preliminary report on disinfectants and disinfection made by the Committee of the American Public Health Association. It is in the form of a popular tract, and is an admirable presentation of the latest conclusions of science on the subject of deodorizers, antiseptics, and disinfectants. It contains also formulæ for the preparation of cheap and efficient disinfectants. We believe it will be of great service to our readers to give the main features of this report, as it will enable practising physicians to tell their families how to kill germs easily and at a low cost. It is quite time, indeed, that the profession cease to think that good disinfectants must be paid for at the rate of a dollar a bottle.

Practical sanitation is based on the view that all infectious diseases are caused by a specific infectious substance, presumably a living germ. Disinfection is perfectly secured only when this germ is destroyed, and a disinfectant is therefore, strictly speaking, a germicide.

There is a class of agents which arrest putrefactive decomposition, and these are known as antiseptics; but a substance may arrest putrefaction without destroying the infective disease-germ. An antiseptic, therefore, is not necessarily a disinfectant. There is another class of substances which destroy odors. These may neither arrest putrefaction nor kill disease-germs. Hence deodorizers are the least efficient for the arrest of infectious disease agents.

Recent researches, says the report, have demonstrated that many of the agents which have been found useful as deodorizers, or as antiseptics, are entirely without value for the destruction of disease-germs. This is true, for example, as regards the sulphate of iron or copperas, a salt which has been extensively used with the idea that it is a valuable disinfectant. As a matter of fact, sulphate of iron in saturated solution does not destroy the vitality of disease-germs or the infecting power of material containing them.

The following points are emphasized by the Committee, and deserve quotation here:

1. Antiseptic agents exercise a restraining influence upon the development of disease-germs, and their use during epidemics is to be recommended, when masses of organic material in the vicinity of human habitations cannot be completely destroyed, or removed, or disinfected.

2. In the sick-room we have disease-germs at an advantage, for we know where to find them as well as how to kill them.

Among disinfectants, chloride of lime, as we have before stated, is believed to rank one of the first. With it may be placed corrosive sublimate and permanganate of potassium.

The following solutions can be readily made and are to be recommended for ordinary use in infectious fevers:

Solution No. 1: Dissolve chloride of lime of the best quality in soft water, in the proportion of four ounces to the gallon.

Use one pint of this solution for the disinfection of each discharge in cholera, typhoid fever, etc. Mix well and leave in vessel for at least ten minutes before throwing into privy-vault or water-closet. The same directions apply for the disinfection of vomited matters. Infected sputum should be discharged directly into a cup half full of the solution.

Solution No. 2: Dissolve corrosive sublimate and permanganate of potash in soft water, in the proportion of two drachms of each salt to the gallon.

This second solution is equally effective, but must be left a longer time in contact with the infected material. It has the advantage of being odorless, but it is highly poisonous, and will injure lead pipes if passed in considerable quantity through them.

Solution No. 3 consists of one part of liquor sodæ chlorinated and five parts of soft water. It is more expensive than No. 1, and has no especial advantage over it, except in case of prescription.

A formula for a powder which may be used in the disinfection of privy-vaults, excreta, etc., is as follows:

Chloride of lime, one pound; corrosive sublimate, one ounce; plaster of Paris, nine pounds. The sublimate is to be pulverized and thoroughly mixed with the plaster of Paris.

For the disinfection of clothing, solution No. 1 diluted with nine parts of water may be used, the clothes being kept immersed for two hours. Or the following solution (solution No. 4): corrosive sublimate, four ounces; water, one gallon; permanganate of potassium, one drachm, may be employed, using one fluid ounce of it diluted with a gallon of water.

Boiling for half an hour will also destroy the activity of all known disease-germs. If clothes cannot be treated with the above solutions or by boiling, they may be disinfected by exposing them to a dry heat of 230° F. for three or four hours. This dry heat of 230° F. does not destroy spores, but it is effectual for the destruction of all disease-germs which do not form spores; and there is good reason, says the Committee, to believe that this list includes small-pox, cholera, yellow fever, diphtheria, erysipelas, puerperal fever, and scarlet-fever (?). Moist heat is more effective than dry; and ten minutes exposure to steam at a temperature of 230° F. will destroy all known disease-germs as well as the most refractory spores.

It is impracticable to disinfect an occupied apartment, but when an apartment that has been occupied by a person suffering from an infectious disease is vacated, it should be disinfected as follows:

All surfaces should be thoroughly washed with a solution of corrosive sublimate of the strength of one part in 1,000 parts of water, which may be conveniently made by adding four ounces of Standard Solution No. 4 to the gallon, or one pint to four gallons of water. The walls and ceiling, if plastered, should be whitewashed with a lime wash containing the same proportion of corrosive sublimate, or they may be brushed over with the aqueous solution. Especial care must be taken to wash away all dust from window-ledges and other places where it may have settled, and to thoroughly cleanse crevices and out-of-the-way places. After this application of the disinfecting solution, and an interval of twenty-four hours or longer for free ventilation, the floors and wood-work should be well scrubbed with soap and hot water, and this should be followed by a second more prolonged exposure to fresh air, admitted through open doors and windows.

If it is desired, in addition or in place of this method, to use fumigation, it will be necessary "to close the apartment to be disinfected as completely as possible by stopping all apertures through which the gas might escape, and to burn not less than three pounds of sulphur for each thousand cubic feet of air-space in the room."

AUTOPHONIA.

Dr. Samuel Sexton's work of special investigation in an important department of otology, an abstract of which is elsewhere reported in this issue of The Record, is a valuable contribution to general medicine, as well as to the special field in which it was made. Of the many practical papers from Dr. Sexton's pen with which medical readers are familiar, the suggestions in respect to autophonia are, perhaps, of wider application than almost any other. Thus, with a knowledge of the significance of the phenomenon under consideration, it would seem that much assistance may be afforded where doubt exists in the diagnosis of ear diseases, especially in differentiation as to the region of the organ affected. This knowledge may likewise serve when the hearing sense is disturbed in mental and other diseases.

Dr. Sexton draws attention, also, to the liability to auscultatory errors, even when the examiner's ears are normal, and where abnormalities exist their avoidance would seem to be difficult. In certain aural neuroses, it is stated, the throat may be wrongly suspected of being at fault when the seat of the trouble lies in the ear; thus, in "singing out of tune," it would be useless to treat the throat for a supposed defect in vocalization when the trouble depended on the autophonia of aural disease. The steps taken, as shown in the paper under discussion, and also in previous contributions, notably in "Des hallucinations de l'ouïe et de la fausse audition, chez les musiciens et les chanteurs, due à l'autophonie, dans les maladies de l'oreille," in *Rev. Mensuelle de Laryngologie, d'Otologie et de Rhinologie* for November, 1884, by means of which Dr. Sexton has traced out the *modus operandi* of the aural anomalies giving rise to the phenomena of autophonia, are of much interest, showing as they do that painstaking observation is necessary in the discovery of scientific facts.

THE CONDITION OF GENERAL GRANT.

During the past week General Grant's bodily health has much improved, and he has been enabled to enjoy short drives in Central Park, to walk short distances out of doors, and to do a considerable amount of literary work on his forthcoming memoirs. His appetite is better, he has relish for his food, and his swallowing is not attended with much pain.

Locally, his disease shows a slight tendency to progress. The sloughy exudation has disappeared, exposing exuberant fungoid granulations in its place. This condition still involves the right and posterior parts of the pharynx, the right tonsillar region, and the right side of the base of the tongue. The palatal curtain is still considerably infiltrated, although all signs of acute inflammatory trouble have disappeared. At the base of the uvula, on the right side, a small fungoid excrescence has developed, which has shown a disposition to extend.

On the free margin of the palatal curtain, midway between the uvula and right tonsillar region, a similar growth of very small size has also appeared. The ulceration at the base of the right anterior faucial pillar, and alongside of the tongue, presents a worm-eaten surface, indicating an extension of the destructive process. The breathing is free and the voice is clear, but the movements of the tongue are somewhat restricted, affecting articulation accordingly. The enlarged glands under and around the right angle of the lower jaw are somewhat harder, and, in consequence of surrounding inflammatory infiltration, are quite firmly fixed. There is, however, less pain in the diseased parts than formerly, and the secretion of mucus is less abundant. The patient obtains a full night's sleep with a minimum amount of morphine, and awakes in the morning feeling much refreshed. Despite the favorable general condition, there have been, unfortunately, no changes in the local disease to warrant any modification of the original diagnosis by the members of the medical staff.

News of the Week.

The New York Post-Graduate Medical School and Hospital has opened a physiological laboratory in the hospital building. The laboratory is intended to encourage physiological research, and is open to all physicians who may desire to make investigations in this department. The director is Dr. G. M. Hammond.

New York Polyclinic.—The regular session of the New York Polyclinic ends on Saturday, May 30th. The number of physicians who have attended the clinics since September 22, 1884, is over two hundred. The summer session opens Monday, June 1st, and will continue to September 12th. The Laboratory of Pathological Histology will be open all summer.

Small-pox has appeared in Missouri, at East Atchison, in Canada, at Montreal, and in Boston, Mass.

The Iowa State Medical Society holds its annual session at Cedar Rapids, beginning May 20th.

The Pennsylvania State Medical Society holds its thirty-sixth annual meeting at Scranton, May 27th to 29th.

The Medical College of Denver University held its annual commencement on March 26th, graduating six students. Dr. Charles Denison delivered an able valedictory address.

The Kentucky State Medical Society.—The Kentucky State Medical Society will hold its third Annual Session at Crab Orchard Spring, Ky., on Wednesday, Thursday, and Friday, June 24, 25, and 26, 1885, commencing at two P.M., on Wednesday, June 24th. Reduced hotel and railway rates have been secured, and everything will be done that can contribute to the enjoyment of the occasion. Gentlemen desiring further information will please address Dr. Edward Alcorn, Chairman Committee of Arrangements, Hustonville, Ky.

Two Cases of Hernia of the Lungs into the Neck, verified by post-mortem examination, are reported by Dr. Maurice Knox in a recent issue of the *Lancet*.

The Saleswomen's Fair, lasting ten days, netted about $10,000. It has been decided, apparently, at the last moment to give the money to a homœopathic institution in this city. There would be no objection to giving a proportional amount in this direction, but the sudden appropriation of the whole sum is unjust to the saleswomen and a cheat upon those who helped at the fair.

Muscle-Grafting.—An operation for muscle-grafting was performed at Bellevue, the muscle from a dog being transferred to that of the arm.

Sanitary Inspection of Railroads in New Hampshire.—At a recent meeting of the State Board of Health of New Hampshire, it was ordered "That a sanitary inspection be made of all the railway stations and grounds, hotels, camp grounds, and other places of public resort in this State, the details of the same to be left to the officers of the Board." In response to the above the leading railroads have already tendered a special train to the Board for the purpose of facilitating the inspections, and have evinced a willingness to coöperate with the Board in making thorough inspections, and in placing the sanitary conditions of the railroads of that State in the best possible condition.

The Illinois State Board of Health and Preliminary Medical Education.—At the annual meeting of the Illinois State Board of Health, held April 16th, the subject of medical education was taken up. It was stated by the Secretary that although 78 medical colleges out of the 116 in the United States, claim to have exacted, at their last session, a preliminary-education requirement as a condition of matriculation, the evidence afforded by the applications thus far received goes to show that in too many cases the standard of such education must be very low. From the graduates of one college, which announces that a preliminary examination will be held in accordance with the rules of the State Boards, five out of the seven applications received contain such intrinsic proof of defective preliminary education, that they were presented to the Board. The Board subsequently adopted the following resolution:

Resolved, That, in order to secure the recognition of its diplomas as in good standing for the purposes of the Medical-Practice Act in this State, it is necessary that each college shall distinctly state in its annual announcement that the conditions of admission to its classes are: 1. Credible certificates of good moral character. 2. Diploma of graduation for a good literary and scientific college or high school, or a first-grade teacher's certificate. Or, lacking this, a thorough examination in the branches of a good English education, including mathematics, English composition, and elementary physics or natural philosophy.

The First Female who Received a Diploma from the Lying-in Hospital, Dublin.—The first diploma from the Dublin Lying-in Hospital for the Licentiate Midwifery issued to a female practitioner, was given to Mrs. Elizabeth Caroline Secord.

The Congress of French Surgeons held its first session in Paris, beginning April 6th. Professor Trélat was elected President, Professor Ollier, Vice-President. After an introductory address by the President, the scientific work began with a paper by M. Gross, of Nancy, who advocated "Posterior Tarsotomy in Club-foot of Long Standing." He showed the advantages of removal of the astragalus and resection of the head of the calcaneum.

M. Ollier made a communication on "Total Resection of the Tarsus, or Anterior Tarsectomy in Cases of Osteo-arthritis," advocating its employment in adults.

M. Demons made a communication in which he advocated the use of osteoclasis in preference to osteotomy in the treatment of genu-valgum of adults.

M. Socin, of Bâle, reported the results of experiments upon the pathogeny of suppuration. He had observed, cultivated, and inoculated the micrococci of osteomyelitis, but did not succeed in reproducing the disease, and he therefore denied the specific character attributed to them.

Perhaps the most important and practical contribution, if corroborated, was that made by M. Thiviar, of Brussels, upon the "Characters of the Urine in their Relation to

Abdominal Surgery." M. Thiviar asserts that in cases of abdominal tumors, if the amount of urea falls gradually to twelve grammes daily, remaining at about that point; the tumor is malignant. After an operation, if the amount of chlorides falls gradually and finally reaches about one gramme in twenty-four hours, suppuration has set in with all its attendant dangers.

Death of Dr. J. S. Bemiss.—We regret to announce the death of Dr. J. S. Bemiss, of Cannelton, Ind., nephew of the late Professor Samuel Bemiss, of New Orleans. Dr. J. S. Bemiss was born in Bloomfield, Ky., January 16, 1838, and was graduated from the University Medical College, of Louisville, Ky., in 1861. After securing his degree of M.D. he entered the Confederate army and soon attained an enviable reputation as a surgeon.

Cocaine to the Soudan.—Among the 24,000 British troops at present in Egypt, the percentage of sickness is only four. The National Aid Society has arranged to send a supply of cocaine to the Soudan.

Bequests to Medical Charities.—The late Mrs. E. D. Morgan bequeathed in her will to the Woman's Hospital of this city, $20,000; to the Home for Consumptives, $5,000.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Reviews and Notices.

Transactions of the American Surgical Association. Edited by J. Ewing Mears, M.D., Recorder of the Association. Vol. II. Philadelphia: P. Blakiston & Co. 1885.

A compact volume of over five hundred pages, and bearing the above title, lies before us. Its twenty-six papers are replete with useful surgical information. An article which will attract as much attention perhaps as any (at least here in New York at the present time) bears the title "Tracheotomy in Croup." Its author, Dr. Gay, of the Boston City Hospital, condenses into a few words the distinction between diphtheria and membranous croup, as those terms are currently accepted. If the operation should be performed and respiration become impeded by the presence of blood in the bronchi, we never should *suck* it out, he says, but should blow air into the lungs. "It is a physical impossibility to *suck* anything out of the trachea, unless air has free ingress to supply the vacuum. . . . . Nature gets rid of offending substances in the air-passages by means of forcible expirations or cough, and we should try to imitate her" (p. 389). He considers subsequent steam inhalations a vital condition of success. Several papers on surgical interference in cerebral troubles (abscess, epilepsy, etc.) indicate the present drift of professional opinion and study. It goes almost without saying that this contribution to the annals of American surgery is a most valuable treatise whose worth coming years—even more fully than the present time—will demonstrate.

A Manual of Organic Materia Medica. Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms, for the Use of Students, Druggists, Pharmacists, and Physicians. By John M. Maisch, Phar.D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. Second Edition. With Two Hundred and Forty-Two Illustrations. Cloth, 511 pages. Philadelphia: Lea Brothers & Co. 1885.

This work is already well known to pharmacists through the first edition, which appeared some three years ago. The present edition is practically the same as the first, except that it contains descriptions of a greater number of drugs and that the structural characters of the drugs have received increased attention. To the students of pharmacy whose good fortune it is to follow the author's lectures this book must be a great help. By the practical pharmacist it must need be looked upon as a reliable manual of reference in regard to the essential physical, histological, and chemical characters of the organic drugs.

Transactions of the Medical Association of Georgia for 1884.

Our Southern brethren seem to conduct their annual gatherings in a very practical and profitable way. They are not mutual admiration societies nor merely social organizations, but the time seems to be spent in an interchange of professional ideas with such discussion thereon as experience may suggest. An especially interesting paper is that by Dr. Battey on "Antisepsis in Ovariotomy and Battey's Operation," in which he reports thirty consecutive successful cases. A rather caustic but well-written review of Herbert Spencer's views on "Syphilis as a Sociological Problem," is made by Dr. Eugene Foster. All the contributions are upon live topics. The general plan and make-up of the volume is excellent. They might be followed with advantage by the publication committees of some States farther north.

An Introduction to the Study of Nervous Diseases. By J. Grainger Stewart, M.D., Professor of the Practice of Physic and of Clinical Medicine at the University of Edinburgh. 1884.

To prepare his students for the study of nervous diseases by presenting to them a concise summary of the subjects of nervous anatomy, physiology, and physiological pathology, has been the object of Professor Stewart in this work. Advances have been so rapid in these departments of neurology of late that such a summary is needed in order to place the student in possession of the many facts recently discovered which aid in the comprehension of nervous disorders. New methods of presenting the anatomy of the central nervous system are superseding the old ones, and at present the course of tracts through the brain is studied instead of the relations of masses of white and gray matter. If the function of one tract is motor, and its course is known from its commencement in the central convolutions to its termination in the motor nerves, then paralysis means a disturbance of the function of this tract, and the location of the disease in the tract is definitely determined. So disturbance of any function means a lesion in the anatomical part presiding over that function, and the anatomy being known, the localization of the disease is not difficult.

It is a feature of this book to connect symptoms with lesions in a very clear and graphic manner, and those who read it will find that many of the rather puzzling facts presented by nervous cases admit of a satisfactory explanation. It is too often the case that students are repelled from the study of nervous diseases by the lack of knowledge of just those facts which are presented here. Dr. Stewart has supplied his students with a manual which will enable them and all others to attend a nervous clinic with much greater interest and profit.

The well-known clinical experience of the author has enabled him to illustrate by appropriate cases almost all of the various conditions which he describes, and he has done this in an attractive manner. The numerous very clear diagrams and figures also aid in the comprehension of the subject. The book will be of great service to those who are beginning the study of nervous diseases, and will also interest those who desire to acquaint themselves with recent progress in this department.

A Guide to the Diseases of Children. By James Frederick Goodhart, M.D., F.R.C.P., Assistant Physician to Guy's Hospital, etc. American edition, revised and edited by Louis Starr, M.D., Clinical Professor Diseases of Children, University of Pennsylvania. Pp. 738. Philadelphia: P. Blakiston, Son & Co. 1885. (New York: J. H. Vail & Co.)

As it is said of some men, so might it be said of some books, that they are "born to greatness." This new volume has, we believe, a mission, particularly in the hands of the younger members of the profession. In these days of prolixity in medical literature it is refreshing to meet with an author who knows both what to say and when he has said it. The work of Dr. Goodhart (admirably conformed by Dr. Starr to meet American requirements) is the nearest approach to clinical teaching without the actual presence of clinical material that we have yet seen. It does not discuss mooted questions of pathology, but is a terse, straightforward account of the author's experience at the bed-side of ailing children. Domestic hygiene is awarded its important place in the therapeutics of pædiatrics. The details of management so gratefully read by the young practitioner are fully elucidated. Altogether the book is one of as great practical-working value as we have seen for many months.

Reports of Societies.

American Medical Association.

Thirty-sixth Annual Session, held at New Orleans, La., April 28, 29, and 30, and May 1, 1885.

Friday, May 1st—Fourth Day.

The Association was called to order by the President. Prayer was offered by Rev. Sylvanus Landrum.

COMPLETED REPORT OF COMMITTEE ON NOMINATIONS.

For Trustees of the *Journal*, Drs. J. M. Toner, of Washington, J. H. Hollister, of Chicago, E. M. Moore, of Rochester, N. Y. For Chairman of the Committee of Arrangements, Dr. Le Grand Atwood, of St. Louis. For Assistant Secretary, Dr. William Glasgow, of St. Louis. To fill the vacancy in the Judicial Council caused by the resignation of Dr. William Brodie, of Detroit, Dr. J. K. Bartlett, of Milwaukee, Wis.

Dr. Harvey Reed, of Mansfield, O., offered the following resolution, which was adopted:

"*Resolved*, That a committee of three be appointed by the President, whose duty shall be to devise a system for awarding, to those who may desire, honors for papers at the next meeting, and that said committee shall report through the Association *Journal*."

The resolution offered by Dr. Roberts, of Philadelphia, adopted in the Section on State Medicine, and referred to the Association, was taken from the table and adopted. It recommends that measures be taken to establish in each State and Territory a

BOARD OF MEDICAL EXAMINERS,

whose certificate shall be the only license to practise medicine in that commonwealth.

CREMATION.

Dr. Keller, of Hot Springs, called up the following resolution, which on motion by Dr. Morris, of Baltimore, was referred to a special committee to report at the next meeting:

Resolved, That, in the near future, if not now, cremation will become a sanitary need in the cities.

Dr. J. A. White, of Richmond, Va., read the

ADDRESS OF THE CHAIRMAN OF THE SECTION IN OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Operations and methods have been lauded as making an era in medicine, have been universally adopted, and have as suddenly died. For example, optico-ciliary neurotomy and Graefe's modified linear extraction of cataract have shared a fate which renders it difficult to say what is, and what is not, an advance in the right direction.

During the last year there has been a steady growth in the departments represented in this Section, especially in rhinology, both in the way of grafting in new ideas and applying the pruning-knife to old ones. In ophthalmology much has been done in researches concerning the pathology of sympathetic ophthalmia, and while it has not been definitely established that the disease is a specific infection, the opinion is steadily gaining ground that the optic nerve and its sheath make a direct communication between the uveal tracts along which micro-organisms can pass and play a most important part in communicating the affection.

The effort to substitute evisceration of the eyeball for enucleation, the apostle of which is Alfred Graefe, was originated by Henry D. Noyes of New York. The treatment of purulent ulceration of the cornea by means of the galvano-cautery has obtained foothold through the aid of cocaine.

Dr. White then gave rules for the use of jequirity in the treatment of trachoma. The most important ophthalmic work of the past year is Landolt's labor to find the exact method of determining the amplitude of convergence. Binocular fixation for established distance is one of the most important functions of the eye, and any disturbance of the normal relation of the two sets of muscles which accomplish this brings about asthenopia. Landolt's method contemplates the exact determination of the power of convergence.

The speaker then directed attention to cocaine and the manner in which it produces its peculiar anæsthetic effect. It is almost useless in children, or in stupid, obstinate, or very anxious patients, in complicated cataract, in iridectomy for glaucoma when the eye is much inflamed, and in all prolonged operations.

The most important advance in rhinology has been in the investigations tending to the solution of the important questions regarding the relation of nasal pathology to certain neuroses heretofore referred to other causes. That a "reflex producing area" exists in the nasal fossa has been determined by Hack, of Freiburg, and Mackenzie, of Baltimore, working independently of each other, and arriving at practically the same conclusions.

The address closed with a special reference to the reflex phenomena of hay fever, in which he did not agree with Mackenzie in the necessity of engorgement or swelling of the turbinated tissues, but thought that abnormal excitability, either inherited or acquired, of the reflex nervous centres best explained the different forms this reflex neurosis takes in different individuals.

The address was referred to the Committee on Publication.

ADDRESS OF THE CHAIRMAN OF THE SECTION ON DISEASES OF CHILDREN.

Dr. J. H. Pope, of Texas, gave an abstract of his address, in which he said that no remedies specially adapted to the treatment of diseases of children had been brought forward during the past year, unless such measures were included as had been devised for the improvement of preparations of infants' foods. Of diseases special mention was made of diphtheria and the benefit arising from its treatment by means of bichloride of mercury. The third topic to which special attention was directed was prolonged nursing as an etiological factor in rickets.

The address was referred to the Committee on Publication.

Dr. W. W. Allport, of Chicago, Ill., Chairman of the Section on Dental and Oral Surgery, being absent, his address was not read, but permission was given to him to report directly to the editor of the *Journal*.

Dr. Quinby, of Jersey City, Chairman of the Committee, reported the following proposed amendment to the by-laws: "That

A NEW SECTION OF MEDICINE

entitled 'Medical Jurisprudence' be established by the Association." Laid over until next year.

Dr. Toner, of Washington, Chairman, reported that the

COMMITTEE ON NECROLOGY

had from time to time reported to the journal, thus obviating the necessity of making an extended report to the Association.

AMENDMENTS TO THE BY-LAWS PROPOSED LAST YEAR.

On motion by Dr. Eugene Smith, of Detroit, the amendment proposed by Dr. Carl Seiler, to divide the Section in Ophthalmology and create a Section in Laryngology, was taken from the table, and after some discussion was postponed indefinitely.

The amendment proposed by Dr. von Klein, of Dayton, O., with reference to *a higher grade of medical education*, was, on motion by Dr. Toner, in the absence of the proposer, laid upon the table.

The following resolution, offered last year by Dr. Cochran, of Alabama, and which he wished to have construed as a proposed amendment to the by-laws, gave rise to a brisk discussion, and finally, on motion by Dr. Murphy, of St. Paul, was laid upon the table.

"*Resolved*, That it is the sense of this Association that it is not expedient for the Nominating Committee to nominate any of its own members for any of the offices of the Association."

Dr. Byrd, of Quincy, Ill., offered as a proposed amendment concerning

THE FORMATION OF THE NOMINATING COMMITTEE.

that each State medical society shall each year appoint a member of the Nominating Committee, together with three alternates, and that the members thus appointed by the several States shall constitute the annual Committee on Nominations of the Association. Laid over under the rule.

Dr. Morris H. Henry, of New York, was elected a delegate to the British Medical Association, and the President and the Permanent Secretary were empowered to issue credentials to delegates to the same Association as heretofore.

Dr. Garcelon, of Maine, and Dr. Jelks, of Arkansas, offered the usual resolutions, including the thanks of the Association for the courteous attention paid to it by the citizens of New Orleans, mentioning especially Mrs. Dr. T. G. Richardson, Mrs. Cartright Enstis, the Jockey Club, the Washington Artillery, the Directors of the Tulane University, the clergymen, and the daily press. Several short but earnest speeches were made complimenting the citizens of New Orleans for their reception and entertainment of the Association, and the resolutions were unanimously adopted.

Ex-Presidents J. M. Toner and T. G. Richardson were appointed a Committee to conduct the President-elect, Dr. William Brodie, of Michigan, to the chair, who, in behalf of the profession of the State which he represented, thanked the Association for the honor it had conferred upon him.

Dr. N. S. Davis, of Chicago, then made a few stirring and patriotic remarks with reference to this meeting in the Crescent City of the South, after which the Association adjourned to meet in the city of St. Louis on the first Tuesday in May, 1886.

SECTION ON SURGERY.

[The following report is an elaboration of that sent by telegraph, and contains abstracts of such of the papers as have been referred to only by title.—ED.]

A CASE OF HYDRONEPHROSIS.

DR. BYRD, of Illinois, related a case of supposed ovarian cyst which he tapped, drawing off fluid which was not examined microscopically, and upon which he afterward, as the patient had an apparent continuance of trouble, made abdominal section and found absolutely nothing. Patient recovered.

DR. HURST, of Illinois, thought Dr. Byrd's case was one of hydronephrosis, and the operation not justifiable.

RUPTURE OF OVARIAN CYST DURING COITUS.

DR. PECK, of Iowa, reported a case of a lady with enlargement of the abdomen, which he regarded as unquestionably an ovarian cyst. The patient was sent home to take treatment preparatory for operation. A few days later he was called and found the woman dying. He learned that on the night previous, upon having intercourse with her husband, who was a large, heavy man, the tumor apparently burst and soon disappeared entirely.

DR. RANSOHOFF, of Cincinnati, O., then read a paper entitled,

TWO OVARIOTOMIES ON THE SAME PATIENT.

The writer reported the history of a case of ovarian disease in which two operations were made successfully with an interval of four years. The first operation was practised by Professor Schönborn, of Königsburg in Prussia, the second by Dr. Ransohoff. The patient at the first operation was twenty-four years of age and married, but had never borne children. At the time of the first operation, when the right ovary was removed, the left gland was already found to be enlarged. Two years before the second operation the abdomen commenced to enlarge rapidly, and when the essayist saw the patient the growth was easily recognized as ovarian. Extensive pelvic adhesions were diagnosticated from the relations of the tumor to the uterus and its protrusion into the pelvic cavity, as revealed by vaginal examination. At the second operation the pelvic adhesions to the uterus and rectum were so extensive that no distinct pedicle could be discerned. A separation of these adhesions would in all probability have involved the life of the patient. For this reason, after the greater portion of the cyst was excised, the remaining portion was fastened to the abdominal wall by a number of silver-wire sutures which were made to include an inch of both cyst and abdominal wall. The lining membrane of the remaining portion of the cyst was then destroyed with the thermo-cautery, to insure against recurrence of the disease and the possible formation of a permanent fistula. With the exception of a pelvic abscess, which developed after the second week and which was opened through the abdominal wound, the patient made an excellent recovery. Since the operation the catamenial flow has appeared four times, each period lasting from three to five days.

In commenting upon this case the essayist called attention to the frequency of bilateral ovarian disease as illustrated by the clinical experience of different operators. As to what constitutes sufficient disease in the second ovary to warrant its removal, different operators are far from agreed. Thus, while Wells has removed both ovaries in about ten per cent. of all cases, Goodell has resorted to double ovariotomy in nearly fifty per cent. of his operations. In this connection the essayist alluded to the increased danger which attends double ovariotomy, the mortality of unilateral operations in the hands of Wells and Koeberle being twenty-two per cent., while that following double ovariotomy by the same operators is respectively thirty-four and fifty-one per cent. In view of this fact, and the youth and conjugal relations of many of these patients, conservatism should be practised in these cases, particularly since children may be born after the removal of one ovary. Of thirty-two cases collected by the author of the paper in which laparotomy was twice performed in the same patient, children were born by five patients between the two operations, the aggregate number of children born being fourteen. The light mortality following second ovariotomies should likewise incline the operator to conservatism. Of thirty-two cases tabulated by the author only 12.5 per cent resulted fatally from the operation itself.

The method of treating the cyst by suture to the abdominal wall was deemed by the author the most important feature of the case. For this method of operating, to which English and American writers had paid little or no attention, he would suggest the name "Ventrocystorrhaphy," to distinguish it from other and inferior incomplete operations for abdominal cysts of every description. By resorting to it the peritoneal cavity is completely shut off from the wound, and the latter is in reality converted into an extra-peritoneal one. When, then, the lining membrane, the proliferating matrix of the cyst, is destroyed by the thermo-cautery, there is almost no danger of a recurrence of the disease or of the establishment of an intractable fistula.

In discussing Dr. Ransohoff's paper, DR. REID, of Ohio, reported a case of second operation on the same patient, occurring in his own practice, with recovery.

DR. JOSEPH H. WARREN, of New York, thought there were certain cases where it was even better, when both ovaries were affected, to defer one side till a subsequent operation.

DR. A. Y. P. GARNETT, of Washington, D. C., read a paper entitled

CHOLO-PROCTITIS TREATED BY HOT-WATER DOUCHE AND STRETCHING OR DIVISION OF THE SPHINCTERS ANI.

He said while the disease under consideration was usually of long standing, it is purely non-malignant in character, confining itself almost entirely to the mucous or submucous tissues, resulting in some cases in superficial ulceration just within the external sphincters, and is often mistaken for simple dysentery and so treated. Several interesting cases illustrating the method of treatment were cited. The patients were confined to a purely milk diet, which was given in one-half pint quantities every three hours. The rectum was injected with water every few hours, as hot as could be tolerated, and which was medicated with ipecacuanha and enough opium for a soothing effect.

In other cases the sphincters were first divided and the same treatment as above adopted.

DR. DAWSON, of Cincinnati, always used the knife freely. He said he thought the principle involved in successful treatment was rest, and to either divide or temporarily paralyze the sphincters by stretching was the essential course to pursue. He said the recognition of the malady was very important though not always easy, as the sensations were directed up into remote parts.

DR. PECK said that as the passage of the hand into the rectum had now become pretty generally considered allowable for exploration in various cases, he would like some expression of the Society on the matter. He cited a case where the procedure had been followed by apparent paralysis and suit for malpractice. He, however, had concluded from personal experiments that a certain sized hand was allowable—say seven inches in circumference.

DR. DAWSON thought no arbitrary rule could be laid down as to the size of the hand, as that must be governed by the size of the rectum, which would vary with the size of the patient.

DR. BYRD, of Illinois, thought an irritation of the sigmoid flexure might explain the apparent paralysis of the sphincters in the case Dr. Peck referred to.

Dr. Ransohoff said the rectum was only governed in size in many cases by the extent of the paralysis.

A paper by Dr. H. L. Getz, of Iowa, entitled

A NEW COMBINED TROCAR AND CANULA AND ASPIRATING NEEDLE,

was read by title and referred to the Committee on Publication.

A lengthy and interesting paper on

AUTOPLASTY, WITH CASES,

was read by Dr. F. Formento, of Louisiana.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DISCUSSION ON ABDOMINAL ANEURISM AT THE MEDICAL AND CHIRURGICAL SOCIETY—VIEWS OF MR. BRYANT, MR. HOLMES, AND MR. HUTCHINSON—DEBATE AT THE CLINICAL SOCIETY ON AMPUTATION AT THE HIP JOINT—THE DEADLOCK AT THE COLLEGE OF SURGEONS—RESECTION OF THE INTESTINE IN CASES OF STRANGULATED HERNIA, WITH GANGRENE OF THE BOWEL—DISCUSSION AT THE MEDICAL SOCIETY OF LONDON—MOUNTAIN CLIMATES IN THE TREATMENT OF CONSUMPTION—CASES IN WHICH THEY SHOULD NOT BE USED—CLIMATE AS A THERAPEUTIC AGENT.

London, April 21, 1885.

At the last meeting of the Medical and Chirurgical Society an important discussion took place on the treatment of abdominal aneurism. The discussion followed the reading of a paper by Mr. Lunn and Dr. Benham on a case of aneurism of the abdominal aorta treated by distal compression. The patient died, but at the autopsy the aneurism was found to be cured. There was gangrene of about two feet of the jejunum. Mr. Henry Morris followed by reading a paper on a case in which death ensued on gangrene of the right lower extremity, the gangrene being due to the pressure of an aneurism on the vena cava inferior and the common iliac veins. The aneurism was full of laminated clot and had thus undergone a process of spontaneous cure.

The publication of Professor Loreta's case of abdominal aneurism in which he effected a cure by passing a couple of yards of copper wire into the sac has attracted much attention, and the recent discussion was therefore very opportune. Those who expected to hear a verdict given on Professor Loreta's recent case by the leaders of London surgical opinion were not disappointed. Mr. Timothy Holmes evidently approved of the procedure of the Bolognese professor, and said that if he had to treat a case such as Mr. Lunn's he should be inclined to adopt it instead of a pressure which was doubtfully distal. Mr. Holmes is one of the most cosmopolitan of our metropolitan surgeons and one of the few who are versed in Italian surgical literature. As the editor of the "System" which bears his name his opinion will doubtless carry weight. As the Senior Surgeon to Guy's, Mr. Bryant will probably find equal support to the opinion expressed by himself in favor of pressure. Mr. Hutchinson, on the other hand, regarding the application of pressure as a dangerous operation, pleaded for the adoption of a drug-treatment. He regarded ergot, acetate of lead, and iodide of potassium as the three best remedies, but insisted that, to be of any use, their administration, not separately, but together, must be persisted in almost to the point of poisoning. Mr. Hutchinson said that in a severe case he had had under his care closely resembling Mr. Lunn's, he had given acetate of lead in such large doses as to produce a blue line on the gums, and lead colic. Rest, a dry diet, and covering the abdomen with layers of ice were also employed at the same time as adjuvants. A complete cure resulted in three months, and the man resumed work. Mr. Hutchinson's reputation as an accurate clinical observer and as a careful and cautious surgeon stands so high that his utterances always command the most respectful attention. His experience, too, at the London has been very large, that being the largest of our metropolitan hospitals and especially noted as a school of surgery. On one point at least most surgeons will be disposed to agree with him. Drugs, rest, and diet may not cure all cases; Mr. Hutchinson does not pretend they will. The suggestion is, however, most reasonable that such measures should be tried before instrumental methods are adopted.

Several speakers doubted whether the pressure applied in Mr. Lunn's case was really "distal;" it was thought more probable that it was "direct." Mr. Henry Morris referred to the valuable paper on the subject in the "International Encyclopædia of Surgery." Ten cases were there mentioned in which proximal pressure had been used, five died, five recovered. Death was due to bruising of the intestines and peritonitis. Mr. Morris said it was a question whether the intestinal injury was due to direct pressure or to embolism on the superior mesenteric artery. Dr. Benham considered the latter to be the cause of the gangrene.

Another surgical question which has lately been brought to the front is that of amputation at the hip-joint. Two papers on the subject were read at the meeting of the Clinical Society last week. One was by Dr. Lewis Marshall; the other by Mr. Hutchinson. In the subsequent debate an agreement was evident among the speakers on most of the points. I may briefly summarize the conclusions reached as follows: Lardaceous visceral disease need not deter the surgeon from operating, but rather the reverse. Early operation is desirable. Davy's rectal lever is useful in many cases, but has its dangers, particularly in pelvic disease. Furneaux Jordan's method is a very good one to adopt in amputating at the hip-joint, and insures a better stump. On this point, though, there was difference of opinion, some of the speakers preferring the older method.

The conflict between the Fellows and Members of the College of Surgeons on the one hand, and the Council of the College on the other hand, still continues. The Council has given its answer and simply declines to move on the road to reform. Some of the proposed reforms touch the pockets of the Councillors somewhat too closely. Those members of the Council who are also examiners are not at all anxious or indeed willing to relinquish the emoluments attached to the office of examiner; neither do they wish to give up the dignity of being on the Council. The Fellows—and still more the Members—are indignant at the microscopic morsel of reform the Council is offering to grant. Well they may be! A renewal of the previous agitation is apparently about to begin on a more extensive scale.

London, April 25, 1885.

At the meeting of the Medical Society of London last Monday evening, the whole time of the meeting was occupied in the discussion of the important subject of the "Treatment of Gangrenous Intestine in Cases of Strangulated Hernia." The debate was introduced by the reading of a paper on the subject by Mr. Mitchell Banks, of Liverpool. Mr. Banks gave the history of a case in which he excised the gangrenous portion of the bowel. The patient was a man, aged twenty-five, who was admitted for a strangulated inguinal hernia on the right side. On opening the sac a long loop of small intestine was found gangrenous. It was removed and the stricture divided. A wedge-shaped piece of mesentery was removed, and the ensuing hemorrhage checked by the application of a score of fine catgut ligatures. The peritoneum of the mesentery was united by a continuous catgut suture. The edges of the gut were turned in, the mucous coats united by interrupted sutures, and continuous sutures used outside these and through the perito-

neum only. The inguinal canal was freely divided to allow of a reduction of the intestine. The sac was then secured by two catgut ligatures, and divided between and excised, the lowest part being left to form a tunica vaginalis. Antiseptic precautions were employed. The collapse passed away in a few hours. The temperature was at first subnormal, and only rose to normal some time after the operation. The highest temperature reached was 100° F. For four days only ice was sucked by the mouth, then some meat-juice was allowed, and the amount of this was gradually increased. Nothing else (except a little opium) was given by the mouth until the twelfth day. Absolute rest and warmth were insisted on, and Mr. Banks thought they prevented waste of the tissues. Recovery was complete in six weeks.

Although the present case was a very successful one, Mr. Banks maintained that the number of cases in which primary resection of the gangrenous gut could advantageously be performed, would be found comparatively few. In most cases it was preferable to incise the gut and await the formation of an artificial anus. On this point most of the subsequent speakers were at one with Mr. Banks. Sir William MacCormac, Mr. Morrant Baker, and Mr. J. H. Morgan all expressed concurrence with this opinion. Mr. Treves entered a plea for a frequent performance of the bolder operation, but he was almost unsupported. Mr. Makins advocated *secondary* resection of the intestine. Although the stricture was divided in this case, Mr. Banks' opinion is that the best plan is to leave it alone. On this point also Sir William MacCormac was in accord with him. Mr. Morrant Baker naïvely confessed that he had not yet made up his mind on the question of division of the stricture, although, following the teaching of his seniors, he had usually performed it.

Dr. Hermann Weber, in his recent Croonian Lectures, expressed himself somewhat strongly in favor of "altitude climates" in cases where there is a tendency to phthisis, whether hereditary or acquired. He specially recommends them in cases with imperfect expansion of the thorax and the so-called 'phthisical habitus." He also considers altitude climates to be generally beneficial in cases where the disease is already existent, but he thinks they are unsuitable in the following cases: Patients of erethric constitution; advanced phthisis; phthisis complicated with any one of the following conditions, viz., emphysema, albuminuria, heart-disease, ulceration of the larynx, constant pyrexia, rapid progress, great loss of substance, considerable empyema; also in persons who cannot eat or sleep at high elevations, or who feel constantly cold. "Some of these conditions," remarked Dr. Weber, "are not permanent but only temporary obstacles." He does not regard hæmoptysis as any bar to a trial of "altitude climates," as experience has shown that hemorrhage occurs less frequently in high than in low regions, and is often checked during a stay in mountain climates.

The question of climate is one which has been much neglected in the treatment of disease, especially by British physicians. By this I not only mean that "climate" has been neglected as a therapeutic resource, but that where a change of climate has been advised, the recommendation of some particular place has been too hastily made, without sufficiently careful consideration of its suitability for the case about which advice is asked. An anecdote I overheard related in a railway train a few years ago, illustrates this point very forcibly: A lady suffering from some eye complaint consulted an eminent oculist, and was advised by him to go to a certain health resort on the continent. A few weeks afterward the oculist himself went to the same place for his annual holiday. The lady had derived no benefit from her stay there, but rather the reverse, it being a dry, dusty place. On his arrival she consulted the oculist. He did not recognize her again and something like the following conversation ensued: Patient: "Well, doctor, I have got no better here, but much worse." Eminent Oculist: "Why, what fool sent you here? It is the very worst place you could have come to." Patient: "Why, you did."

I cannot, of course, vouch for the truth of the above story, the narrator being quite a stranger to myself, but I may mention that the name of the oculist in question was given, and although a very uncommon one, given quite correctly.

IS DEATH FROM HEART-WOUNDS INSTANTANEOUS?

To the Editor of The Medical Record.

Sir: Interesting medico-legal questions were brought before our local physicians during the December, 1884, term of court in the trial of Thomas Magill for the killing of Melville Bessey, the plea being self-defence and the evidence circumstantial. Bessey, a blacksmith on the Magill farm, was at work in his shop when called upon by Magill for a certain purpose. According to Magill's testimony a quarrel ensued, and Bessey was shot just at the time he left the anvil with hammer uplifted for the purpose of striking Magill. He was shot with a charge of B. B. shot from a choke-bore shotgun, the right margin of the main wound just reaching the left border of the sternum, at and removing a portion of the third costal cartilage, penetrating the anterior wall of the right ventricle a little below the left centre, the ventricular septum and posterior wall of the left ventricle at the centre, the upper margin of the wound not quite reaching the auricles, possibly a few scattering shot penetrating the auricles. Three fingers could be introduced through the wound in the heart, the ventricles being considerably lacerated. The charge lodged in the posterior chest-wall.

At the coroner's inquest it was testified that death would be necessarily instantaneous, that the man would "drop in his tracks;" but as the body was found eight feet from this spot partially under a work-bench, the question as to dropping in his tracks became an important one. Five "medical experts" were summoned and kept on the witness stand at times varying from five minutes to an hour, the defence trying to prove that Bessey, in a striking attitude, hammer in hand, approaching Magill, was shot through the heart, and while staggering received a second glancing charge of shot in the scalp at the back of the head; the prosecution endeavoring to prove that Bessey was shot while standing at the work-bench, the first charge glancing off the back of the head to the right, that he turned and received the second charge in the heart, and fell dead under the bench. It was also testified that Bessey, when found a few minutes after, was having convulsive movements of the feet, had the hammer clenched in his hand and threw his head and shoulders back, but gave no other signs of life. Questions were profusely propounded in reference to shock, hemorrhage, power of volition and locomotion, possibility of his still retaining the hammer, etc. The differences of doctors, bewilderment of attorneys, rulings of the learned judge, and horror of the jury when the judge ordered the heart brought into court (which order, however, was revoked on the protest of the jury and the attorney for the prosecution), seemed to throw a terrible responsibility on the innocent "expert," and for a time the court seemed held by him in abeyance.

The following question of interest was asked by the prosecution, and objected to and ruled on:

"Now, doctor, having seen the position in which Magill testified to holding the gun, having heard the testimony in regard to the position of Bessey, having examined the wound in the chest-wall and heart, in your opinion, could such a wound be produced under such conditions?"

All seemed to rest upon the "opinion" of the "expert." He was relieved by the defence objecting to the question as being an improper one for a medical expert.

The learned judge adjourned the court, and after a night's rest ruled, "The witness may answer the question if he chooses, but the Court will not compel him to do so."

Even the topography of the heart was brought into dispute, and one expert only saved himself a great embarrassment by examining the section of the chest to ascertain how the charge of shot could enter at the third costal cartilage and penetrate the ventricles of the heart in such manner. The intercostal spaces were much greater than normal, thus bringing the third rib where the fourth should be. Bessey was a man of large frame. Experience of experts with shotgun wounds of the heart was limited, but serious as the wound was it could not be proven that it was "necessarily instantaneously fatal." It seems very difficult to prove that any heart-wound, no matter how severe, is "necessarily instantaneously fatal." In this case the jury disagreed, and a new trial was set for the spring term of court. Experience with shotgun wounds of the heart would be very desirable. In this case, "if life were prolonged a few moments," it would seem as though instantaneous death from heart wounds must be caused by some element besides severity of the wound and hemorrhage. If this be shock, it would seem as though death must have been instantaneous, or shock from heart-wounds does not depend upon the amount of injury. LOUIS C. PETTIT, M.D.

BISMARCK, D. T.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from April 26, 1885, to May 2, 1885.

BYRNE, CHAS. C., Major and Surgeon. Assigned to duty as attending surgeon at the Soldiers' Home, D. C., to take effect May 15, 1885.

DE WITT, CALVIN, Captain and Assistant Surgeon. Upon being relieved by Surgeon Byrne, ordered to report to the Surgeon-General of the Army. S. O. 94, A. G. O., April 25, 1885.

TORNEY, GEO. H., Captain and Assistant Surgeon, United States Army. Assigned to duty at Fort Monroe, Va. S. O. 87, Department of the East, April 25, 1885.

ARTHUR, WM. H., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Niagara, N. Y. S. O. 89, Department of the East, April 28, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 2, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
April 25, 1885	0	11	79	4	173	45	0	0
May 2, 1885	0	10	72	4	159	56	0	0
Deaths.								
April 25, 1885	0	3	22	2	21	26	0	0
May 2, 1885	0	6	15	3	12	25	0	0

TO RELIEVE TOOTHACHE.—A writer in the *Courrier Médical* recommends the chewing of canella bark for the relief of toothache. The pain is at once quieted, he says, if the bark is of good quality, and as effectually as with creasote, carbolic acid, etc.

A SELF-PERFORMED CÆSAREAN SECTION.—Dr. Guggenberg relates the following: "A woman, who had already been delivered seven times without accident, became pregnant for the eighth time. Toward the end of her pregnancy she was seized with pains, which continued regularly for a day and then ceased. They were replaced by spasmodic attacks of very violent pain, accompanied by expulsive movements and an enormous distention of the abdomen. The fœtal movements ceased and the pains increased to such a degree that the patient thought she was going to die. She then seized a razor and cut through the abdominal wall in a longitudinal direction, extracting a dead child together with the placenta through the wound. At this time Dr. Guggenberg was called, but had nothing to do beyond replacing some loops of intestine and closing the wound. He concluded that there had been a partial rupture of the uterus, and that the woman had removed the child through the rent, not cutting the uterine structures. The hemorrhage was at first very profuse, but finally ceased spontaneously. The woman made an excellent recovery.—*Rivista Internazionale di Medicina e Chirurgia.*

MEDICAL GRADUATES IN FRANCE.—The diploma mills in France seem to grind with an exceeding slowness unknown in the older and freer republic on this side of the Atlantic. There were graduated in 1884 but five hundred and ninety physicians from the six medical schools of that country, as compared with six hundred and sixty-two for the preceding year.

STILL ANOTHER ANTIPYRETIC.—Haeckel gives a description of a new substance, called by him "dundakina," obtained from the bark of the *sarcocephalus esculenta* growing in Senegal. It is a bitter resinoid substance, soluble in water and alcohol, possessing astringent and antipyretic properties, and has been proposed as a succedaneum of quinine.

THE BAROMETER IN THE COFFEE-CUP.—When a lump of sugar is dropped into coffee and allowed to dissolve without being stirred, the bubbles of air contained within it rise to the surface of the liquid. If a foamy mass is found which remains in the centre of the cup, it is said to be an indication of fair weather; but if, on the contrary, the bubbles are scattered from the centre, and collect in a ring around the edge of the cup, the probabilities are that there will be rain. The coffee must, however, be good, for if adulterated these appearances will not be presented.—*La Hygiene para Todos.*

A CRITICISM OF DR. ROBERTS' PAPER ON "ANATOMICAL GEOMETRY AND TOPONYMY."—Dr. Harry M. Sherman, of San Francisco, Cal., writes to call attention to several points in the article on "Anatomical Geometry," by Dr. M. J. Roberts, in THE RECORD of February 21, 1885. The paper, he says, "contains inaccuracies and errors, some of which are slight and would be overlooked in any other than an article which aims at absolute accuracy, while others are plain mistakes." In his definition of a standard attitude the author has, he thinks, left too much to the individual judgment of each observer to satisfy the requirements of a scientific standpoint. In the first place, the soft parts over the femoral condyles and malleoli are to be either "in contact or equidistant from each other"—a definition which permits two standards and introduces confusion into the comparison of cases. "Again, the feet are to be slightly everted. Passing over this term (though it is certainly open to criticism) and accepting it to mean that the toes are slightly turned out by rotation of the thigh, we must ask *how much* eversion 'slightly' means. Ordinarily the word would be sufficiently accurate, but we are hereafter to measure angles in degree and not to estimate them approximately, and the point from which we measure—the point at which it is considered that there is rotation neither outward nor inward—should be indicated and not left to the judgment of different observers, whose ideas

of 'slightly' may vary considerably. This laxity is fatal to the attempt 'to determine by instruments of precision the extent of outward or inward rotation of the limb,' in such a manner that cases measured by different observers may be compared." Dr. Sherman further criticises the author's method of naming the lines and angles in the different figures. "A line should be indicated by two symbols, placed one at each end; an angle by three symbols, placed one at the apex of the angle and the other two at the two free ends of the lines forming the angle. Moreover, in reading the symbols, that at the apex should be named between the names of the two others. Thus, in the description of the 'angle of normal proximo-distal convergence,' in Fig. 4, it should be named *a r b;* merely saying that it 'is represented by the lines *r a b*' means nothing. Under the head of *Inversion* the 'line *l c e*' is mentioned, but *l c'* is a straight line and *c' e* is the arc of a circle. This is lamentably inaccurate. It is not necessary to follow the demonstrations, pointing out similar errors; they exist in connection with every figure, and render the *anatomical geometry* portion of the title absurd. 'Drastrophometry,' taught as it is in this article, with an indefinite standard as a never-failing source of error, with the lines, planes, and angles misnamed and almost inextricably confused, showing a total disregard of geometry and geometrical nomenclature on the part of the author, cannot be considered an advance in surgery." The motive of Dr. Roberts' article, the writer thinks, was good, but he considers his instruments "absolutely useless so long as the principles of their application are described in such a hopelessly crude way."

The Causes of Sudden Death in Childhood.—M. Bontemps has written a thesis treating of this subject, in which he formulates the following classification from a study of a large number of cases: 1. Sudden death from disease of the nervous system. Possible causes: cerebral congestion (a much less rare condition than is usually supposed), cerebral anæmia, meningeal hemorrhage, hydrocephalus, cerebral tumors, anencephalia, convulsions, glottic spasm. 2. Possible causes in relation to the respiratory apparatus: laryngismus stridulus, pleurisy, tubercles in the lungs or bronchial glands, suffocating catarrh, congestion or apoplexy of the lungs, foreign bodies in the air-passages, whooping-cough. 3. Circulatory system: syncope, pericarditis and endocarditis, cyanosis, venous thrombosis, purpura hemorrhagica, ulceration of the jugular veins. 4. Digestive system, peritoneum, and kidneys: cholera infantum, typhoid fever, hematemesis, intestinal worms, peritonitis, nephritis with uræmia. These different causes of sudden death in children are of varying frequency, some being very rare. An arrangement according to the relative frequency would be desirable, but the author says that he had not sufficient clinical material to enable him to determine this point with any accuracy.—*La Hygiene para Todos*, April 1, 1885.

In Hæmoptysis, when the usual remedies, as ergot, gallic acid, etc., have failed, Professor DaCosta advises the use of the tincture of matico, in doses of ʒ ss. to ʒ j., every two or three hours.—*College and Clinical Record.*

The Remedy against Mosquitoes.—The time is coming when mosquito remedies are to be in demand, and we print the following letter from "An Old Salt," published in *The Lancet:* "The unfortunately too frequent differences among doctors when they do ventilate their opinions may, so far as the above matter is concerned, be very easily explained. The application of carbolic acid and oil, in the proportion of one to ten or fifteen, is for a time perfectly successful in keeping off mosquitoes; but the carbolic acid evaporates so rapidly that a renewal has to be made every half-hour or thereabouts. So far as my experience goes, there is no place where the sting of the mosquito is so venomous as on the banks of rivers and lakes, and after exposure in such places I have known men to be laid up and disfigured for weeks. By using the oil, and repeating its use every half hour or so, I have fished with perfect impunity where all other fishers were half smothered with mosquito muslin wrapped round them—and in the tropics this is very heat-producing, even if effectual in keeping out the 'wily mosquito'—and the only difficulty I had was to keep it out of my eyes, as it produces smart pain if it touches the conjunctiva. Put a bottle of freshly mixed acid and oil in your pocket, and apply it at frequent intervals, on hands, neck, and face, and you may defy mosquitoes, gnats, *et hoc genus omne.* My experience includes the east and west coasts of Africa, the East and West Indies, North America, and the Arctic. The Arctic black gnat in summer is as annoying as any 'punkah mosquito.' Before I used carbolic oil I employed creasote and oil, and a mixture of it used to be sold at least a quarter of a century ago by the fishing-tackle folk in the land of the 'Blue Noses;' indeed, it was my experience there which led me to substitute the carbolic acid for the creasote." We would add a caution against possible black urine and poisoning by carbolic acid.

Treatment of Gonorrhœa.—In the early treatment of gonorrhœa, Professor Gross condemns the use of injections. His plan is as follows: If possible, put the patient to bed; give him at the outset a purge, by administering Epsom and Rochelle salts, each ʒ ij., in lemon syrup. Allow no meat or any stimulating articles of diet, etc. Malt liquors do more harm than alcoholic, so interdict both. No tea or coffee, but give him milk, eggs, and some oysters, etc. Three times daily he is to hold the penis in a cup of hot water—quite hot. Keep the organ there for five minutes at a time, then wipe it gently each time. The internal treatment will be by the "antimonial and saline mixture:

℞. Antimonii et potassii tartrat..... gr. $\frac{1}{10}$.
Magnesii sulphatis..... ℥ ij.
Morphinæ sulphatis..... gr. $\frac{1}{16}$.
Tinct. aconiti radicis..... gtt. j.
Liquor potassii citrat ..... f ʒ ss.
Olei limonis..... gtt. ss.
Elixir simplicis ..... f ʒ ss.

M. Sig.—Ter die.

By this treatment the urine will be rendered bland and unirritating. Should the urine persist in "scalding," then add to the above prescription tinct. cannabis indicæ, gtt. x. To prevent or cure chordee, order at night a suppository of—

℞. Extract. opii,
Camphoræ.....āā gr. iij.

In the course of four or five days the discharge from the urethra will look more like laudable pus; then order an injection:

℞. Hydrargyri chloridi corrosivi ..... gr. ij.
Aquæ destillat..... Oj.

Sig.—With a syringe that holds an ounce, inject into the urethra—having first "flushed" the canal several times by voiding urine—and retain the fluid for five minutes.

Internally, a useful combination is that used at the outdoor department at the hospital, and consisting of—

℞. Cubebæ ..... ℥ ij.
Alum. pulv..... ʒ j.

M. Sig.—Of this take a heaping teaspoonful in a tumbler of water, ter die; the dose to be increased.

Should the discharge per urethram still persist, use an injection of—

℞. Liquor plumbi subacetatis ..... f ʒ j.
Aquæ ..... f ℥ x.

M. —*College and Clinical Record.*

The Treatment of Malaria One Hundred Years ago.—All readers of old medical books delight in Dr. James Lind's essay on the diseases of hot climates. Lind had been in all the tropical regions of Asia, Africa, and North and South America, and finally was physician to the great naval hospitals at Nashua and Portsmouth. His experience was immense and his good sense equally so. With the exception of the substitution of quinine for Peruvian bark, it is doubtful whether his treatment in 1784 was not as good, and in some respects better than it is in 1884. Fever and ague was then epidemic, and prevailed in low, woody, and marshy places in England, and infants at the breast were not spared. Lind said its prevention was more difficult than its temporary cure, and relapses were difficult to guard against in impure air. The soil, air, and water of the places were at fault, and it was hard to correct all these; but boiled or distilled water was very useful. He thought that the numerous fires and great smokes of large towns tended to purify the air. In 1759 he sent away two regiments placed on low ground, and decimated by fevers and fluxes, to high ground only five miles away, when not a man was afterward taken with these diseases. He made people sleep in the highest rooms in their houses, and shut up the doors and windows looking toward low grounds. He made them wear warm clothing, with a plentiful diet of meat and warm soup, with spices, which are now known to be good germicides, and some wine, with a little tobacco. He would not let people go abroad in the morning with an empty stomach, even to prayers, but made them take at least a slice of bread, with coffee or tea, or even chamomile or Peruvian bark tea. He advised laborers to take an onion or bit of garlic with their bread, and did not object to beer, or an infusion of bark or rhubarb, with a little spirits, especially if they had to dig ditches, or drain marshes. This was not half as bad as drinking pond or marsh water. He had great faith in tinctura sacra, or aloes with cloves, which reminds one of Warburg's tincture, and thought an infusion of Peruvian bark with orange-peel was a good morning preventive draught, although sometimes tinctures were better. He advised people not to swallow their saliva, and chewing chamomile flowers was better than tobacco. In the cold fit he advised a teaspoonful of spirits of hartshorn in warm wine whey, or balm tea, and has known agues entirely removed by this simple treatment after the most powerful remedies had failed. Lind was among the first to teach that agues cannot be stopped too soon, and says of over two hundred cases stopped after the first or second paroxysms, none felt any bad effects. But he always gave ipecac if there was nausea, and aloes pills if there was not. The amount of his practice may be inferred when he tells us that he gave one hundred and forty pounds of bark in 1765. He was among the first to use opium in the hot stage, to ease the headache and other pains, to abate the fever, and produce sweat. Among three hundred patients, he noticed that opium did not prevent or mitigate the succeeding stage when given in the cold fit, but when given half an hour after the hot fit, it generally gave immediate relief. He says if opium is given in the hot fit it shortens and abates it, with more certainty than an ounce of bark is found to remove the disease. It generally gives sensible relief to the head and takes off the burning heat of the fever, while it favors profuse perspiration. He says this opium sweat is attended with an agreeable softness of the skin, far different from the disagreeable burning sensation which is so common when it is not taken. It often also produces a refreshing sleep. He thought it helped to produce a full intermission. If the patient was costive, he gave the opium in two ounces of tinctura sacra, the operation of which was not prevented by it. In 1765, 1766, and 1767 he seldom visited less than thirty or forty ague patients a day. If opium was not well borne internally, he used equal parts of laudanum and soap liniment, rubbed on the spine or abdomen, or both, or gave it in clysters. He thought, next to bark, alum with nutmeg was the best remedy against ague; at least, he prescribed no medicine with better success; ten to twenty grains of extract of gentian with two ounces of tincture of aloes was not bad, and often removed very obstinate intermitting fevers. Hot small beer was occasionally useful. Two-grain doses of ignatia cured four patients of quartan ague, but failed in twice that number. Oleum succini applied to the spine prevented the fits of an ague as often as most external applications, except turpentine. Nutmeg, pepper, horseradish, and lemon-juice were useful. Bay leaves were not bad, nor the inner bark of ash, calamus, mustard seeds, etc. He thought that spirits generally occasioned severe headache or aggravated the hot fit.

George Eliot was sufficiently interested in the following advertisement, which appeared in the *Times* of 1852, to copy and send it to her friends, the Brays: "To Gentlemen—A *converted* medical man, of gentlemanly habits and fond of Scriptural conversation, wishes to meet with a gentleman of Calvinistic views, thirsty after truth, in want of a daily companion. A little temporal aid will be expected in return. Address, Verax."

Remarkable Post-Mortem Preservation of the Human Body in Death from Arsenic.—Dr. Walter H. Peters, of Lafayette, Ind., reports the two following instances of remarkable preservation of the human body as the result of arsenic poisoning: "The cases were subjected to judicial investigation at the December term of the White County, Ind., Circuit Court, 1884. August 18, 1884, I was called upon to make a post-mortem and clinical examination of the body of a citizen of Monticello, Ind., who had died thirty months previously. Upon the cover of the coffin being removed no odor of putrefaction was perceptible. The skin of the whole body was discolored, but firm and moist. The face was somewhat shrunken, but easily recognizable. The viscera, as well as the muscles of the extremities, were moist and maintained their histological characteristics and elements. The deceased was recovering from a slight attack of pneumonia at the time of his death, and the pathological condition was as clearly evident as though death had but just occurred. Throughout the whole alimentary canal there was not a single perforation from decomposition. The duodenum, sigmoid flexure, and rectum showed evidence of inflammation which was unmistakable, being greatly reddened and thickened (compare Taylor, 'Poisons,' 1875, p. 127). The stomach and all of the remaining viscera were normal. The gentleman lived five days after symptoms of poisoning set in, and the arsenic was pretty equally distributed throughout the body, with the exception of the liver, which contained only a trace. The stomach and intestines contained no poison, and the kidneys and spleen the largest proportion, or one-third of a grain. The total amount of arsenic in the body was estimated at about five grains. The degree of preservation and the length of time after death at which the evidence of inflammation was visible, places this case almost without parallel in the annals of medical jurisprudence. Two weeks later the body of a sister of the deceased, who had died at the same time, was exhumed, and the whole of the body, except the abdominal and thoracic viscera, was found decomposed. The viscera, however, were about as well preserved as in the former case, although I was unable to swear as to the presence of inflammation at the time of death. The woman had died within twenty-four hours after symptoms had appeared, which will probably account for the less perfect distribution of the poison. 1.271 grain of arsenious acid was found in the alimentary canal, and .2 grain in the liver. The remaining organs were not examined. The bodies were buried in a moist sandy soil, at a depth of five feet, in ordinary wooden coffins. These cases may, I think, go on record as instances of preservation due entirely to the action of arsenic as an antiseptic. They also throw some doubt

on the correctness of Dr. Taylor ('Treatise on Poisons,' p. 299), that 'absorbed arsenic does not prevent decomposition of the soft organs in which it is deposited.'" [Dr. Peters has not, apparently, excluded the possibility of the bodies being preserved by formation of adipocere. —Ed.]

Atropia vs. Morphia in Morphia Poisoning.—Dr. J. R. Brandt, of Green Bay, Wis., was called to see a married woman, who at 9.40 P.M. had taken gr. vij. of sulphate of morphia. Dr. Brandt saw her at 1.15 A.M., three and a half hours later. He found the pupils contracted to about a line, and would not respond to the light, face pale, lips bloodless, surface cool, and covered with a cold clammy perspiration, temperature 97°, pulse 60, and heart feeble. At 1.30 A.M. he gave an injection in the left arm, fifteen drops of a solution of atropia sulphate (grs. iv. to ℥ j.). At 1.45 A.M. he gave half a teacupful of strong coffee. The pulse immediately became 78, steady and feeble. At 2 A.M. she vomited a large quantity of brown fluid, with odor of coffee. The pulse fell at once to 60, feeble, and so continued until 2.20 A.M., when it rose to 70, and vomiting began again, after which it fell to 60. Gave another half-cup of coffee. At 2.30 A.M. ten drops of atropia solution were injected, and in one minute she complained of an indescribable sensation, diplopia, pupils dilated to about two lines, and at 2.45 A.M. dryness of the mouth and fauces were complained of, desire to drink, and some retching, but no emesis, pulse 78, temperature 97.8°. At 3 A.M. she vomited again, and vomiting was repeated every twenty minutes; gave coffee each time. Five minutes before each vomiting spell, her pulse would fall to 60, and in a moment after would rise to 78. At 4 A.M. vomiting ceased, pulse rose to 80, temperature 98°; ordered her to go to bed, but she could not sleep. At 4.30 A.M. left the patient until 7 A.M., found the patient with violent frontal headache, very restless. Temperature 99°, pulse 85, face flushed, mouth dry. The patient continued to improve, and made a happy recovery. Dr. Brandt writes: "I gave $\frac{5}{24}$ grain of sulphate of atropia; I think had I given $\frac{1}{24}$, *i.e.*, $\frac{1}{24}$ to each grain of morphia, it would have been dangerous."

The "Archives of Hydrology."—A new journal, entitled the *Archives d'Hydrologie*, made its appearance in April. It is to be devoted chiefly to a consideration of the merits of the mineral waters of Auvergne and of the central plateau of France.

A Warning to Drinkers.—*Le Journal d'Hygiene* publishes a comparative table of the probabilities of life for moderate drinkers and total abstainers. According to this, a moderate drinker at twenty years of age may expect to live 15.6 years; at thirty, 13; at forty, 11.6; at fifty, 10.8; at sixty, 8.9. The probability for total abstainers is, at twenty years, 44.2; at thirty, 36.5; at forty, 28.8; at fifty, 21.25; and at sixty, 15.285.

Scarlet Fever Carried by a Third Healthy Person.—Dr. A. H. Baker, of Wellsburg, N. Y., writes: "In The Medical Record for April 18, 1885, I read an article by J. M. Ward, M.D., on the question whether a physician is liable to convey scarlet fever to his obstetrical cases. In this connection, my experience, as related in the following recent case, may be of sufficient interest to merit publication. On April 6, 1885, I was called to attend Mrs. G—— in her first confinement, about 9 P.M. I remained with my patient all night, and as the labor was a tedious one, frequent examinations were necessary. On the morning of the 6th, previously to visiting the above patient, I had visited four cases of scarlet fever, all in one family and crowded into one room. My visit there was somewhat prolonged on account of the number needing my attention. Before going to my obstetrical case I took a thorough bath and made a complete change in my clothing, this being the usual day for such change. I washed my hands in a bichloride solution, twenty-five grains to the gallon of water. The young mother did very nicely until the 10th, about four days from her confinement, when I was called and found her presenting symptoms of scarlet fever. On the 11th, the characteristic eruption made its appearance. On the 14th, a sister-in-law of my first patient, who had been acting as nurse, was suddenly taken ill with sore throat, vomiting, and fever, and on the 15th gave evidence of the character of the attack by the appearance of the scarlet eruption. On the 20th, the infant, then about two weeks old, presented unmistakable signs of the fever, by the appearance of a profuse eruption in the morning, after having had a restless night. All are making a good recovery. This family resides three miles out of town, and had had no communication with any infected person or family, except the above as related. I believe the fever germs were carried in the physician's hair."

Papilloma of the Bladder.—At the meeting of the Cincinnati Academy of Medicine, April 20th, Dr. C. D. Palmer reported a case of papilloma of the bladder. The patient, a married woman, a multipara, aged fifty, past the menopause, came to the Doctor in January, 1884, complaining of dysuria, hæmaturia, and tenesmus vesicæ. On microscopical and physical examination, he found papillæ, blood-corpuscles, and mucous strings, but no tube-casts. After a course of treatment, she was in the following March put under ether, the urethra dilated, the finger introduced, and a papillomatous growth about the size of a half section of a hickory nut removed by the finger-nail. The bladder was washed out, and the patient made a good recovery, remaining comparatively well for several months. Gradually, however, her old symptoms returned. These became so aggravated that the doctor determined upon another and more radical operation. In March last, one year after the first operation, assisted by Drs. Kehler, McKee, and Zinke, he made a vaginal cystotomy. A growth the size of the thumb was found and removed. The bladder was left open, and the urine allowed to flow at will. Patient had an elevation of the temperature for one day, other than which there were no untoward symptoms. She is now feeling quite comfortable again. The urine flows sometimes from the opening in the base of the bladder, sometimes through the urethra. The reporter spoke in favor of the vaginal cystotomy, compared with the dilatation of the urethra. The operation required less skill, it was done in less time, there was less danger attendant upon it, the recovery was more rapid, and the removal of growths much more satisfactory and thorough. Besides this, when there was present, as in many cases, a chronic cystitis, the rest given the bladder by the continual drainage of the urine was a great advantage. The cut was usually left open. It sometimes healed spontaneously, in other cases remained permanently patulous. That the patient would remain in her present favorable condition, the doctor was not ready to say. The papilloma he sometimes thought changed into the epithelioma.

Poisoning by Opium and Belladonna.—At a meeting of the Lyons Medical Society (*Lyon Medical*, March 15, 1885), M. Icard related a case of accidental poisoning by the injection of about two and a half drachms each of laudanum and tincture of belladonna. The patient was not seen until several hours after the mixture had been taken. After the unsuccessful employment of emulsives, M. Icard had recourse to hypodermic injections of ether, and the patient finally recovered.

Dr. Rouxeau has been appointed Adjunct Professor of Anatomy and Physiology to the École de Médecine of Nantes.

Inoculation of Cancer.—MM. Violet, Mathis, and Faivre, of the École Vétérinaire of Lyons, have succeeded in several instances in producing cancer in the lower animals by inoculation.

Death from Impaction of the Bowels.—Dr. Fred. L. Kingsbury, of Samokov, Bulgaria, writes, asking what was the cause of death in the following case: "A villager was brought to a Khan in this city from his home, six hours distant (approximately eighteen miles). I found the man extremely anxious, and complaining that he had not been able to have a passage from the bowel for two days. He was a man in the prime of life and strength. Both he and his friends declared that he had never from his childhood had *one sick hour*. On examination, I found the colon enormously distended with fecal accumulation, the transverse portion being evident exteriorly. His temperature was normal. This was Saturday. He had been as well as usual until the previous Thursday. On Friday, at home, he had taken about twenty grammes of magnesii sulphas without effect. His pulse was about 80 from the time when I first saw him until he died. He was given at once strong purgatives, but without effect. Copious rectal injections were then given, but the rectum was so stopped by fecal accumulation that the water simply ran back. It was impossible to thrust in a long tube on account of the extreme hardness of the impaction. On Sunday he was given six drops of croton oil without effect. The treatment was then changed to anodynes and stimulants. Despite everything he steadily sank and died. The peculiar feature of the case was that there was no tenderness on pressure, no elevation of temperature, and almost no vomiting. The thermometer used was Casella's patent, with magnified index, the best instrument he makes. I will be glad to answer any questions relative to this case."

Hot Water and Hæmorrhoids.—Dr. W. H. Bennett, of Brooklyn, N. Y., writes: "Of late it has been the rage to drink hot water before breakfast by the pint, and even by the quart, or more. The list of diseases which such a treatment will cure is claimed by those who enthusiastically practise it to be unusually long. I am afraid some among the profession have been deceived in this matter as well as many of the laity, and the eyes of both have been closed to the harm that might result from such treatment, *long continued*. In certain diseases of the stomach, and possibly of the first few feet of the upper bowel, copious draughts of hot water may do great good, as in gastric ulcer and gastric catarrh. But on the large intestine, especially on the rectum, the effect is not salutary, for the water cannot reach these latter parts *hot*, and its ultimate action is to debilitate the muscle and to relax the mucous membrane. Several cases of hæmorrhoids and prolapse of the rectum have come under my notice which first appeared after a few weeks' use of hot water internally. On imbibing hot water in large quantities the general circulation is perceptibly stimulated, but it soon becomes sluggish in those parts not brought in immediate contact with the fluid, and the tissues become œdematous and overstretched, then relaxed and flabby."

The Treatment of Insomnia.—Dr. Samuel Francis in a lecture upon this subject says: "I would advise four remedies for insomnia; each one is simple and easy of access. 1. To abstain from all mental work, no matter what the consequences, and give up any habits that over-excite the nervous system. If duty enforces labor of the intellect then confine it, if possible, to the hours of from 10 A.M. to 3 P.M., and a free use of vapor-baths, under the supervision of the family physician, will materially assist. 2. Drink freely of skim-milk, from one to four quarts a day, and eat of the plainest and most digestible food, masticating thoroughly and slowly, and avoid wine of any kind, for it only deceives the drowsy brain by its intoxicating influence, demanding full pay the next day. Just before retiring let the patient take an old-fashioned tumbler of bread and milk. This serves to cause the flow of blood to go to the stomach instead of the head; and, if the head be placed rather high in the bed, that will effectually aid gravity to lessen its fulness. If you want to prove this, let a student stoop to pick up a pin on the floor, and see the crimson purple of his face. 3. If his means can afford it, a quiet, long, open-air drive, in a comfortable carriage, with perfect silence, and the bracing wind in his face, while he is warmly wrapped up, will bring on a soothing influence that will often cause sleep during the drive; and if his mind is not excited by the useless conversation of a companion, he will pass a beneficial night in his room, providing it be cool. No matter how well off a person may be, let him have a blazing fire in the adjoining dressing-room, but no artificial heat in any sleeping apartment, and plenty of warm bed-clothes. 4. I would suggest a regular judicious employment of massage. To state something that can be remembered, I would briefly say that where there is pain and inflammation the rubbing should always be toward the heart; but when it is to be practised exclusively for nervousness or sleeplessness, it can, and had better be from the heart toward the extremities. For it serves to stimulate resistance and reaction, which increase the circulation and bring the blood to the surface, lessening the amount in the head."

A Floating Hospital in the Red Sea.—The ship Garibaldi is to be converted into a hospital for the use of the Italian forces in Egypt. It will be provided with two hundred beds, and is to be in charge of Drs. G. Butera and A. Morisani, who have been ordered to Massowah to superintend the work.—*Gazzetta Medica Italiana, Lombardia.*

Distilled Water in the Treatment of Renal Disease and Rheumatism.—Dr. E. P. Turner, of this city, writes: "I have been treating patients suffering from kidney trouble with distilled water for a year past, and with satisfactory results. In Bright's disease I restrict the patient to a milk diet, and direct him to take the water freely, from one to two quarts a day. I have one case that seems to be nearly cured, and another which has surely improved, though under treatment but a short time. I also think the water is beneficial in rheumatism. I first used the distilled water on the theory that it added nothing irritating, is a good solvent, and would therefore relieve the kidneys of any irritant that water will dissolve. I mention this so that, if it is considered worthy of trial, it may have a fair test. I use it in preference to mineral waters, and believe it will have a better effect." Distilled water has been used quite extensively in hospital and private practice in this city, in the treatment of Bright's disease. It is a good diuretic, and often improves the symptoms.

Honors to Dr. Ferrán.—A grand banquet in honor of Dr. Ferrán, with whose researches into the morphology of the cholera microbe the readers of The Medical Record are familiar, was given at the Grand Continental Restaurant in Barcelona, on the evening of April 9th. The *menu* was inviting, but at the same time rather suggestive of a stomach-ache. It was printed on a card which seemed to be marbled, but which, on closer inspection, was found to present a picture of all the various morphological aspects of the cholera microbe as described by Ferrán. Among the dishes were purée à la Peronóspora, candied fruit à la Pasteur, chops à la Koch, filet à la Paulli, fish with comma bacillus sauce, partridge à la Ferrán, punch à la prophylaxis, capons à la Van Ermengem, and ice-cream à la Nicati and Rietsch. No casualties were reported. Most of our Spanish exchanges devote a large portion of their space to an account of the banquet and a report of the congratulatory speeches, and the *Revista de Ciencias Médicas* presents its readers also with a well-executed portrait of the recipient of these honors. Judging from the enthusiastic welcome which Dr. Ferrán everywhere receives, Spain is not unmindful of the labors of her sons, and we hope that his discoveries may receive such confirmation as to entitle him to similar honors in other lands. In the meanwhile we are glad to learn that he survived the cholera banquet, and we extend to him our sincere congratulations.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 27, No. 20 NEW YORK, MAY 16, 1885 Whole No. 758

Original Lectures.

ON IRRITABLE BLADDER.

By ALEXANDER W. STEIN, M.D.,

SURGEON TO CHARITY HOSPITAL (GENITO-URINARY DIVISION,); PROFESSOR OF VISCERAL ANATOMY AND PHYSIOLOGY, NEW YORK COLLEGE OF DENTISTRY; PROFESSOR OF COMPARATIVE PHYSIOLOGY, AMERICAN VETERINARY COLLEGE, ETC., NEW YORK.

THE bladder is a remarkable organ. When we consider how simple it is in structure, we marvel at the complexity of its mechanism. How tolerant at times of irritation, how patient even of extensive structural change within its walls, and yet how easily and from what insignificant causes is it excited to irritability! In illustration of this point, many instances might be cited. The following occur to me at hand, they stand out in bold contrast to each other. A woman died from perimetric abscess and tubercular peritonitis. The perimetric abscess was a consequence of parturition, and it burst into the ileum. Simultaneously with the diminution of the abscess the urine became bloody, and carried with it a large amount of pus. It was believed that the abscess had opened into the bladder. Pus was never observed in the stools. At the autopsy there was no communication found between the bladder and the abscess. The entire mucous membrane of the bladder was dark red, in a state of the highest degree of catarrhal inflammation, secreting pus and exuding blood. And yet the woman had no irritability of bladder; she never complained of that organ (J. Mathews Duncan).

Another female complained of incontinence of urine, with great bearing-down pains. The bladder did not contain a teaspoonful of urine before she was compelled to void it, and the act was accompanied with much forcing and great scalding. Every five minutes the expulsion was repeated, and the moanings of the patient were pitiful to hear. She obtained no peace day or night; she suffered upward of six months. Autopsy showed bladder empty and *quite healthy*. Right kidney double normal size, but healthy. Left kidney was one large pouch of pus, which had not yet emptied itself; no trace of kidney structure was left (Pratt: London *Lancet*, October 18, 1879).

The vesical neck is the most sensitive part of the bladder. The fundus is infinitely more tolerant of pathological encroachments and stimuli than is the vesical neck. Note the quantity of residual urine, often acrid and offensive, that unconsciously accumulates in the basfond in certain forms of centric hypertrophy of the prostate. A calculus in contact with the vesical orifice provokes painful and energetic contractions; but when, by change of position, the stone is thrown into the body of the viscus, irritability is at once diminished and the frequency of micturition lessened. Appreciating, then, the fact that the neck of the bladder is the most sensitive part of the viscus, and that it is from this point that the afferent impulses originate which set into operation the coördinate movements necessary to bring about the physiological act of micturition, it is obvious that anything that will stimulate or irritate this portion of the organ, either directly or indirectly, will augment this sensibility to an unnatural degree, and produce the frequent and perhaps painful micturition which characterizes our complaint—*irritable bladder*. Again, bearing in mind the intimate nervous connections which exist between the bladder and the neighboring pelvic organs, we cannot be surprised that any disease or disturbance in the latter arouses sympathetic action in the former, so that vesical irritability is excited not only by contiguous irritation, but as often by reflex irritation. Frequent and painful micturition is always a more or less prominent symptom when the bladder has itself undergone structural change; thus a contracted bladder or a concentric hypertrophy of its muscular coat, resulting from overwork in overcoming some existing obstruction to the outflow of urine (stricture, hypertrophied prostate), diminishes at times to a remarkable degree the capacity of the organ, and as the quantity of urine poured into it is not diminished, micturition becomes so frequent as to verily constitute an incontinence.

Here I show you the urinary tract of a man who, three months previous to his death, had a close stricture divided by an internal urethrotomy. He was relieved of much pain, but the micturition continued as frequent as ever; in fact he kept the penis in a urinal all the time. The result of the mechanical obstruction to the outflow of urine is evident in the enormously dilated ureters and pelvis of kidney, etc., but note especially the contracted and hypertrophied condition of the bladder. I am sure it could not hold more than an ounce of fluid. Given a normal quantity of urine conveyed to such a bladder, you can imagine what must be the frequency of micturition, barring inflammation, which existed in this case. But at present I do not wish to lead you so much to the consideration of "irritability" as it is symptomatic of pathological conditions of the bladder itself, as to those forms of the complaint in which it presents simply as a functional disturbance. As such, its causes may be classified into mechanical, reflex, local, and constitutional.

As mechanical causes we have the various uterine displacements, pelvic and abdominal tumors, etc. These conditions, by pressing upon, distorting, and even dislocating the bladder, tend not only to diminish its capacity, but worry and irritate it to increased functional activity, so that after a time a very small quantity of urine creates an irresistible desire to urinate, the patient holding water with the greatest difficulty. The habit acquired in these cases, of emptying the bladder at short intervals, produces in time a diminution in the capacity of the bladder, which may itself become a factor in the complaint.

As reflex causes we have the presence of ascarides, hemorrhoids, ulceration of rectum, fissure of anus, abscess in ischio-rectal fossa, or between prostate and rectum, irritation or congestion of prostatic sinus, or vesiculæ seminales, excessive sexual intercourse, or ungratified sexual desire, masturbation, phimosis, congenital insufficiency of meatus, stricture, urethral caruncle, vaginismus, pyelitis, calculus in pelvis of kidney or ureter, the passage of gravel or blood-clots along the ureter, are among the numerous causes which have been known to provoke frequent and painful micturition. It is common with women much employed on the sewing-machine, and exposure to cold almost invariably aggravates the trouble.

The bladder naturally resents the presence of urine that has undergone any change in its physical or chemical condition. Urine that is over-acid or over-alkaline, too dense or the reverse, is not well borne by the bladder. Hence all constitutional disturbances that reflect on the composition of the urine are causes of irritable bladder; malassimilation, primary or secondary; a scrofulous, rheu

matic, or gouty condition of system; the inhibition of certain drugs, such as cantharides; diuretics in large or long-continued doses; alcohol, asparagus, strawberries, etc., are factors in the causation, which require recognition and proper interpretation. Especially is the presence of pus or blood intolerable to the bladder, and thus it happens that frequent and painful micturition are often the first symptoms which point to the existence of serious disease in the urinary tract above. While I wish to avoid unnecessary repetition, I would again impress upon you the fact, that not only is frequent and painful micturition a symptom common to many ailments in which the bladder is but sympathetically involved, but that with these symptoms there may be pus in the urine, even in considerable quantity, which may make the bladder symptoms so prominent as to completely mask the real disease and mislead you in the belief that you have a veritable inflammation or disease of the bladder, when this organ is almost or wholly unaffected. Do not harass the already overtaxed bladder with treatment for a disease of which it is innocent.

On the other hand, you must remember that, as increased vascularization is the natural sequence of prolonged irritation, it happens not infrequently that the irritated bladder is at the same time congested or inflamed, furnishing pus; and now, again, you must be on your guard that you do not accuse the bladder of the original cause, which may be apparent elsewhere. In these cases it is always important to ascertain whether the pus contained in the urine is derived from the bladder or from the urinary tract above. This is determined by thoroughly washing out the bladder, and then, the patient standing, allowing the urine to trickle through a soft catheter as it comes from the ureters. If the urine thus accumulated contains pus, the conclusion is that the source of the trouble is beyond the vesical cavity.

Finally, if after deliberate search you cannot reconcile cause and effect, you are forced to the conclusion that your trouble is of neurotic origin. It is often concomitant with psychic disturbances, nervous depression, close mental application, anxiety, fear, excitement, fright, etc. In these conditions the frequency of micturition is often due as much to an increase in the quantity as to the change in the quality of the urine; notably so in the hysterical attacks of women, in whom the renal secretion is not only pale and limpid, but very abundant.

Therefore we have to make a distinction between those conditions in which the frequent micturition is the result of rapid accumulation from excessive production—the quantity of urine passed each time being quite considerable—and true irritability, in which the quantity passed is small, often but a few drops. Again, in the latter condition, pain, if it does not exist at the outset, very soon becomes a marked feature. It may be slight, it may be severe, according to the causation and duration of the complaint; it is often of a burning or scalding character; it may be limited to the vesical neck, or, having its origin here, may radiate in various directions, especially toward the glans penis and rectum. Sometimes the pain is felt during micturition, but usually it is most pronounced with the final expulsive effort of the bladder. Irritable bladder and incontinence of urine have so much in common as regards their etiology, that the one is frequently associated with the other. These patients often complain that they wet themselves. When the complaint is of purely neurotic origin, it is especially characterized by the inconstancy and variableness of its symptoms—present one day, gone the next; severe at one time, slight the next.

The paroxysmal form is analogous to neuralgia of the vesical neck, and the terms irritable bladder and neuralgia are often used synonymously. Again, there may be spasm of the bladder. This, when a distinct complaint, differs also from simple irritability in the decidedly paroxysmal nature of the attacks, during the intervals of which the person is at perfect ease. The paroxysm consists of a constant desire to void urine, with violent tenesmus or bearing-down pains. The urine is expelled sometimes involuntarily, always in small quantity, and in an intermittent and spasmodic manner. Often, however, the patient will stand and strain to pass water ineffectually, for now the spasmodic condition of the external sphincter is in the ascendency, and the antagonism of the latter to the "detrusor" is such that, while allowing the escape of jets of urine during momentary periods of relaxation, the bladder is not permitted to empty itself completely, and more or less retention exists until the cessation of the attack. The following is an aggravated case in point, and it is further instructive in that the accumulation of urine was so gradual that retention was unsuspected by the patient, even with his bladder distended to the umbilicus:

Mr. ——, aged forty-eight; many years in feeble health. Came to me to be relieved of frequent and painful micturition. Suggestive of the cause of his trouble was cantharideal ointment, which he had used freely on the chest for the relief of a chronic cough. He was obliged to pass water, or at least make the attempt, every fifteen or thirty minutes, which was always accompanied with much strangury, a "smarting, burning pain along under-surface of penis." The desire to urinate came suddenly and urgently. Often he would wet himself in spite of all haste to prevent it, while again he would stand and strain without passing a drop. The strangury lasted about a minute and then subsided, whether any water was passed or not. Thus he continued, taking medicines, but attending as usual to his business for about twenty days, when I saw him again. I now found the bladder distended to the umbilicus, but he did not complain in the least of any pain or discomfort. The only thing that attracted his attention was a "swollen abdomen," and that he passed less water than usual. His bladder was slowly and gradually relieved of an enormous quantity of urine, but it never regained its tonicity, and ever since, now a number of years, he has depended exclusively upon the catheter for the evacuation of his bladder.

The indications for treatment range themselves with the causes of the complaint; hence it is important to bear in mind that the bladder symptoms are often but the signals of distress pointing to some remote trouble, which, if sought for, recognized, and removed, will cause the bladder symptoms to disappear without any special treatment directed to it. The first thing to be done is to investigate the condition of the pelvic organs and examine as to the existence of any external or reflex source of irritation, which, if present, will be dealt with in a manner called for by each. At the same time the condition of the urine is to receive immediate attention. If found at fault, the next thing is to ascertain the cause or causes which produce the disturbing quality in its composition, whether it is due to some constitutional taint, to a gouty or rheumatic diathesis, to improper diet, imperfect digestion, malassimilation, sedentary occupation, or some other peculiar habit of life. The lithic and oxalic diatheses are to receive the neutralizing agents adapted to them; the scrofulous the remedies peculiarly applicable to them. Any deviation from the normal reaction and density of the urine is to be corrected; if found too acid and dense, it is rendered bland by alkalies and diluents, such as potass. or sod. bicarb., citrat., or acetat., liq. potass., lithium carb., etc. There seems to be at times an individual idiosyncrasy or susceptibility for one or the other of these drugs, so that in a given case one drug will act promptly and efficiently, while another will be apparently inert; but whichever one is used, it must be taken persistently, in full doses, at short intervals, and largely diluted. Acid urine is easily enough neutralized; I wish that we had the same power over alkaline urine. For this purpose benzoic acid is depended upon, given in increasing doses from twenty or thirty, to sixty grains per diem. It rarely appears in the urine

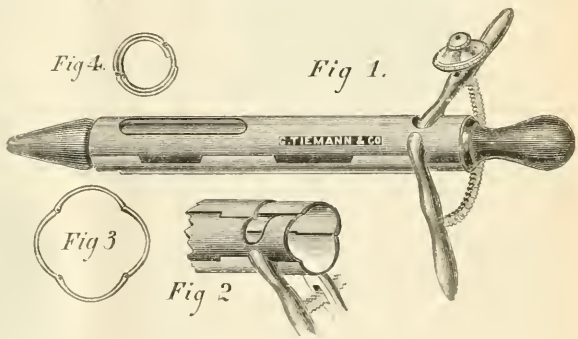
under its own form, but generally as hippuric acid, which is supposed to be formed by the conjugation of the benzoic acid with the glycocol of the liver.

Attention must be directed to the diet. Alcohol in any shape is obviously interdicted. A rich animal diet tends to increase the production of urea and uric acid, and to intensify the acidity of the urine, while asparagus, spices of all kinds, and certain fruits are to be avoided. In short, the food and drink must be unstimulating to kidneys and bladder, very digestible, and adapted in quantity and quality to the requirements of the system, always remembering that while high living and excesses are to be carefully avoided by the plethoric and robust, a more generous regimen and tonic treatment will be required by the anæmic and impoverished of blood. Milk in liberal quantities, even for a time as an exclusive diet, has proved of excellent service in these cases. Digestion, if impaired, must be assisted, the bowels kept free, not by active cathartics, but by the mildest means that will serve to relieve the hemorrhoidal vessels and nerves from pressure and irritation. General hygienic rules are to be laid down, with possibly change of air and scene.

To enumerate all the so-called specifics for vesical irritation would fill a page; among the most popular are buchu, triticum repens, flaxseed, alchimella arvensis, pereira brava, uva ursi, and gelsemium. These are generally taken in form of infusion or decoction, from a half to one pint daily, and it cannot be denied that in properly selected cases they have proved serviceable. Iron has always been a favorite remedy, and when you wish a decided tonic effect, a combination with nux vomica and quinine is excellent. In the purely neurotic forms of the complaint, belladonna, chloral, hydrobromic acid, and the bromides suggest themselves. Having done what we can to correct any condition of system which may give rise to irritating urine, we turn next to the immediate alleviation of pain, which is especially demanded at night. For this purpose we resort to anodyne suppositories or to morphia subcutaneously in the perineum. The hot sitz-bath or hot fomentations over hypogastrium and perineum sometimes afford great relief. In severe cases the patient is best in the recumbent posture, with the pelvis elevated to favor gravitation of urine from the vesical orifice. Cocaine is decidedly potent in its sedative influence on the mucous membrane of the bladder. In the few cases that I have thus far had occasion to use it, it has proved very satisfactory. The strength of the solution may vary from two to four per cent., and the quantity injected from one drachm to half an ounce. The gentle introduction of a well-warmed conical steel sound, beginning with a small instrument and gradually increasing the size to the full capacity of the urethra or meatus, is, in neurotic cases, often of great benefit. At first the passage of the instrument is apt to be painful, but the effect following is to obtund the morbid sensibility and to afford relief. In the spasmodic form of the complaint there is considerable resistance to the passage of the instrument, and this should never be forcibly overcome. If by gentle and steady pressure the sound is not permitted to pass, or creates much pain, it is best to substitute for a time a flexible tapering bougie until the urethra becomes accustomed to the presence of an instrument.

A married gentleman, aged thirty-five, came to me to be relieved of great frequency in micturition both day and night, and a severe scalding pain in the prostatic urethra occurring with each seminal emission, whether during the orgasm of coitus or involuntarily. The symptom had its origin in an attack of urethritis more than three years before, but finally it became so severe that he refrained from sexual intercourse. There was no obstruction other than a decided spasmodic contraction of the compressor urethræ. The urethra was sensitive throughout, but especially so the prostatic portion, where the passage of the instrument occasioned almost intolerable pain. The prostate was not sensitive to rectal touch. There was no perceptible discharge, but a disposition to gluing of meatus and slight staining of linen had existed from the beginning. Urine was normal. As patient had unavailingly tried a variety of remedies before seeing me, internal medication was suspended, and he was treated simply with steel sounds gradually increased from 7 E. to 19 E. These were introduced at first every third day, then every second day, and finally every day. At first the irritation seemed to be increased, but this was rapidly followed by relief. In a few weeks the frequency of micturition became normal, and within two months the pain in seminal emission entirely disappeared. Several years have elapsed and he has had no recurrence of the trouble.

For the female we have a most valuable procedure in rapid dilatation of the urethra. It is indicated not only in all cases in which the exciting cause of the "irritability" is obscure, but even in those in which the cause is apparently still operative and unyielding to ordinary treatment; the relief thus obtained is often prompt and signal. The objection that has been urged against this operation is the danger of producing permanent incontinence of urine. When this operation was first performed for the relief of irritable bladder, it was with the expectation that at least temporary incontinence would



follow, and that the bladder would thus obtain a period of physiological rest; but experience has taught that moderate dilatation is not followed by incontinence, but that, *per contra*, the irritable viscus retains its contents more comfortably, and for a longer time, after the stretching of the urethra than it did before. That permanent incontinence of urine has resulted from extreme dilatation is a fact which we should keep constantly in mind, and I would enjoin upon you the exercise of every care, gentleness, and patience in your manipulations. At the same time, for the treatment of irritable bladder, such an accident should not happen, because, as I believe, it is never necessary to carry the dilatation to the point of laceration, or to a degree in the least endangering the tonicity of the parts. Again, the instruments that have hitherto been employed, such as "uterine dilators," "sequestrum" and "bullet" forceps, are not adapted to serve the purpose of dilators for the delicate female urethra! Digital dilatation is not much safer; unfortunate results have followed this practice, for it also is too sudden and extreme. I will now show you an instrument which I believe most nearly fulfils the requirements of a urethral dilator. It consists of a metal tube, three and a half inches in length, with an obturator, elastic and conical at the point, which projects an additional inch beyond the distal end, and which serves to facilitate the introduction of the instrument. One inch from the proximal end is a handle that supports a graduated bar and thumb-screw, by means of which the expansion of the instrument is effected. When closed, it is thirty-nine

millimetres in circumference, and is capable of expansion to six and a half centimetres. Fig. 4 represents a vertical section of the instrument closed. At Fig. 2 it is seen expanded to fifty millimetres, and Fig. 3 shows a vertical section in complete expansion, namely, six and a half centimetres. From this you will see that the expansive force of the instrument is distributed as equally as possible over all parts of the circumference of the urethra by smooth, rounded blades, and not upon two or three points or sides of the canal. Furthermore, the dilatation can be effected very gradually, and with absolute precision, the degree of expansion being determined by the graduated bar, with the greatest accuracy, even to a millimetre. In this manner we conform to the conditions by which alone a maximum degree of dilatation, without laceration, can be attained. Indeed, the tearing or rupturing of the urethra, which, with other instruments is almost inevitable when thorough dilatation is effected, and the incontinence of urine, which such an injury often entails, will by this, if by any method, be avoided. Owing to the peculiar conformation of the instrument it creates very little pain, even when dilated to its utmost. I have operated in this manner many times without anæsthetics. The instrument is an admirable speculum by which a most satisfactory view of the interior of the bladder can be obtained. The following is the method of procedure : Your patient is put on the back or on the left side, the latter position is often preferred from motives of modesty, while the urethra is thus perfectly accessible. The instrument is introduced and rapidly dilated until the urethra is moderately stretched, when the dilatation is proceeded with more slowly and cautiously, according to the degree of resistance felt, the screw being advanced a few millimetres at a time ; the force exerted being in inverse proportion to the resistance to be overcome. Thus gradually the parts relax, and the instrument is expanded, if needs be, to its full capacity. Simon, who did so much to popularize this operation, divided the meatus with scissors before commencing dilatation, making two lateral slits of one-quarter centimetre in the upper margin, and one downward of half a centimetre in depth. With my instrument I have had no occasion to do this ; but if the parts are at all rigid, there is no objection to slitting the meatus, as an incision is better than a laceration ; nevertheless, laceration of the meatus does not necessarily impair the retentive power of the bladder, while incontinence of urine is apt to follow extreme dilatation, even when the urethra is not torn. This is especially to be apprehended after the slow dilatation with sponge or seatangle tents. The dilatability of the female urethra varies much with the individual and with age. In some persons the meatus is rigid and very unyielding, while in others you can carry the expansion to the full capacity of my instrument, with scarcely any pain and very little delay. It is an interesting fact that two fingers have been forced into the bladder and yet the retentive power of the viscus has remained intact ; but such a degree of stretching is always dangerous to the integrity of the bladder, and for the relief of the symptoms now in question, extreme dilatation is entirely unnecessary. In the last five or six consecutive cases in which I have dilated the female urethra for vesical irritability, I have not exceeded five or five and a half centimetres, a degree of dilatation entirely innocuous and satisfactory. In illustration I will mention briefly the last two cases that have been operated on in this hospital.

Mrs. ——, aged forty-two, admitted to hospital January 4th. Gives evidence of syphilis of long standing. There are several ulcerations on the labia, and one in the rectum, which are dressed with calomel, iodoform, and zinc oxide.

March 30th.—Has complained of frequent and painful micturition since January 25th, internal medication affording occasional relief. At first the urine was reported clear and normal; recently pus-cells have made their appearance. The irritability of the bladder and pain have much increased of late. Passes water eight to nine times during the day, and from five to seven times during the night; occasionally has incontinence. Her urethra was dilated to five and a half centimetres, without anæsthesia, and with scarcely any indication of pain.

April 1st, the day following the operation, the frequency in micturition remained about the same, but that night she passed water twice only, and without pain.

April 3d.—Retained water at one time seven hours without inconvenience.

April 5th.—Passed water six times since corresponding hour yesterday, and from this date her micturition was painless and averaged six or seven times in twenty-four hours for several weeks, when she was discharged.

The next case is even more striking.

Mrs. ——, aged twenty-two, admitted with papulo-squamous syphilide vaginitis and irritable bladder, the latter trouble she has had six weeks ; at present urinates ten to twelve times during the day, and six to eight times at night, with considerable bearing-down pains. Urine feebly acid, contains pus ; urethra exceedingly sensitive. Small flexible catheter could not be introduced on account of pain.

April 25th.—Patient was etherized and urethra dilated to five centimetres. On inspection the mucous membrane of the bladder was found very much congested.

April 26th, passed water eleven times, and 27th nine times in twenty-four hours.

April 29th, 30th, and May 1st, passed water six times in twenty-four hours ; has no pain about the bladder.

May 2d, 3d, and 4th, passed water five times in twenty-four hours.

May 5th, passed water four times, and 6th, 7th, 8th, 9th, and 10th, five times in twenty-four hours, and absolutely free from pain.

And lastly in the rôle of surgical interference comes cystotomy, vaginal or perineal, as the case may be. Both can show gratifying results. A short time since I received a letter from a young man on whom I made a medio-bilateral operation in this hospital in April, 1878. He writes that he is well, and is profuse in his expressions of gratitude for the relief that was given him. As I remember him, he was an eccentric and nervous youth, about eighteen years of age, a cook by occupation, and rather precocious in his sexual instincts, having had gonorrhœa three times, the first time at the early age of ten. He complained of great frequency of micturition, with acute lancinating pains in the glans penis, radiating to the perineum, and at times to the inguinal and hypogastric regions. His urine was feebly acid, free from albumen, but held small quantities of pus. Prostatic urethra was exquisitely sensitive to the passage of the smallest instrument. He was given a variety of remedies, together with hot baths, fomentations, and suppositories, but with only transient and unsatisfactory results. He became greatly emaciated and haggard in appearance, lost his appetite, and begged earnestly to have something more done for him. The cystotomy gave him immediate relief, and, as it now appears, he has remained well ever since, a period of seven years. I have cited these personal experiences to you not because they are unique or exceptional, for they can be multiplied many times, but they serve to illustrate the wide range of treatment to which these cases are susceptible.

PROTESTING AGAINST VACCINATION.—A public meeting was held not long ago in Leicester to protest against the compulsory vaccination law. Several thousand people marched in procession and assembled in the public square to listen to speeches from opponents of the measure. A picture of Jenner was burned, and also a printed copy of the objectionable vaccination law.

CASE OF
CONGENITAL CYST OF THE TONGUE.

By J. WILLISTON WRIGHT, M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK; VISITING SURGEON TO BELLEVUE HOSPITAL, ETC.

The patient was a healthy and well-developed girl, six years of age. At birth the tongue was somewhat larger than normal, and protruded slightly from the mouth, but did not interfere with the act of nursing, and did not seem to incommode the child to any extent until about two years ago.

At that time, however, the tongue began to enlarge quite rapidly, and in the course of a few months assumed such proportions that it was with great difficulty she could withdraw it between the teeth and close the lips over it. Her speech became unintelligible to any one except her mother; mastication had been impossible for the last year and a half, and she had been obliged to subsist entirely upon fluids, bread soaked in milk, and other soft food.

On April 3, 1884, when I first saw the patient, the following notes were made of the case: American; aged six years; blonde, well-developed, in excellent bodily health, and, mentally, very bright. Tongue protrudes from the mouth two and a half inches beyond the incisor teeth, and measures five inches in circumference. Its surface is covered with large, dry, brownish-colored scales. Saliva constantly dribbles from the mouth. Speech greatly impaired. By making a great effort the tongue can be drawn into the mouth and the lips closed, but at all other times it hangs down over the chin, as shown in Figs. 1 and 2, and presents a most unsightly

Fig. 1.

Fig. 2.

appearance. To the touch the tumor seems to be solid, and is possibly a simple hypertrophy, but an indistinct sense of fluctuation near its centre renders it quite possible that it may be cystic. The under jaw is somewhat expanded laterally, and is bent downward from the angles to the symphysis in such a manner that when the tongue is withdrawn into the mouth and the molar teeth of the upper and under jaws brought in contact, the incisor teeth of the two jaws are separated by about an inch and a half. The teeth in the under jaw, especially the incisors and the canines, are very irregularly placed; some have been forced out of their sockets and lost; some are situated nearly horizontally, with the cutting-edge projecting forward, while all are covered with a dense layer of tartar and, together with the gums, are in a generally unhealthy condition.

April 8, 1884.—With the patient under ether, two stout, slightly curved needles, each carrying a double silk ligature, were passed through the base of the tongue from opposite sides, and from above downward. The needles were then cut off, and one of the ligatures on each side tied with moderate firmness around the corresponding lateral half of the tongue, as a temporary means of controlling hemorrhage. The ends of the remaining ligatures were simply knotted together, to be used in case of necessity after the operation, for preventing the stump falling back into the fauces.

An incision was then made on the upper surface of the tumor, through which about three ounces of thick, yellowish, purulent-looking fluid made its exit. On introducing the finger into the cavity, its walls were found to consist of a thick, glistening, well-organized membrane, extending for some distance backward into that portion of the tongue which occupied the cavity of the mouth, and as the tongue was still greatly in excess of its normal size and length, even after the cyst had been completely emptied of its contents, it was decided to amputate at about the level of the incisor teeth.

Fig. 3.

This was accordingly done by making, with a long finger-knife, antero-posterior flaps and afterward dissecting out the posterior segment of the cyst. The vessels were then secured with fine carbolized silk ligatures, the temporary ligatures through the base removed, and the edges of the wound closed with several points of interrupted suture. With the exception of a temporary suppression of urine on the day following the operation, her recovery was rapid and satisfactory. Two weeks later I removed the first permanent molar tooth from each side of the under jaw for the purpose of allowing the front teeth to come closer together.

May 18th.—Since last report the patient has worn an elastic chin bandage, attached to a leather skull-cap for the purpose of drawing the depressed chin upward into its proper position. The lips can now be closed with ease, and she talks so well that even a stranger has no difficulty in understanding every word she speaks.

May 19th.—Returned to her home in Connecticut.

February 16, 1885.—Saw the patient to-day. The temporary incisor teeth have been shed and the permanent set have taken their place. These are all large, regular, and strong, and those of the upper and lower jaws are as closely in contact when the mouth is closed, as in any other subject, while her speech is absolutely free of impediment. Fig. 3 is from a photograph taken a few days ago, or about ten months after the operation.

A microscopical examination of the contents of the cyst revealed the presence of a quantity of granular detritus, some fat-cells, a few large granular corpuscles, but no pus-cells.

53 West Nineteenth Street.

The Mineral Springs of this Country.—A correspondent writes: "Referring to the celebrated unction treatment ('Schmier-kur') as practised at Aachen (Aix-la-Chapelle), Germany, in syphilitic ailments, can you inform me whether we have any springs in this country, barring the Hot Springs of Arkansas, whose waters possess medicinal properties equal to those of the German spa."

THE MECHANICAL TREATMENT OF TALIPES CALCANEUS.[1]

By A. B. JUDSON, M.D.,

ORTHOPÆDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

Simple talipes calcaneus, if not severe, belongs to the category of non-deforming club-foot. If the heel is not greatly enlarged, and if the case is not complicated with talipes valgus, the foot may be so dressed with an ordinary shoe that it has both good shape and small size. But this variety of club-foot is accompanied by a very serious impairment of function, due to paralysis of the muscles of the calf. The patient is unable to stand on tiptoe on the affected foot, or even to use the anterior part of the foot in walking. His condition resembles that of a slave in the hands of the aborigines of North Carolina who were in the habit of performing amputation of the anterior part of the foot in the case of a captive whom they wished to keep as a laborer in their fields.[2] They performed disarticulation at the tarso-metatarsal joint, now known as Lisfranc's amputation. A patient affected with talipes calcaneus is unable to make pressure on the ground with the anterior part of the foot, not by reason of absence of the part, but from paralysis of the muscles controlling it. The result is a peculiar and serious defect in the gait.

Dr. Holmes, whose recitation class in anatomy I had the great benefit of attending in the spring of 1860 (I recall his admirable skill as an examiner with a mixture of pleasure and pain), analyzed the complex act of walking in the following words: "Walking, then, is a perpetual falling with a perpetual self-recovery. Man is a *wheel*, with two spokes, his legs, and two fragments of a tire, his feet. He *rolls* successively on each of these fragments from the heel to the toe. If he had spokes enough, he would go round and round as the boys do when they 'make a wheel' with their four limbs for its spokes. But having only two available for ordinary locomotion, each of these has to be taken up as soon as it has been used, and carried forward to be used again, and so alternately with the pair."[3]

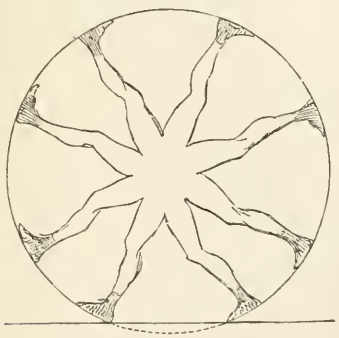

Fig. 1.

A reference to Fig. 1, which is copied from Dr. Holmes' article in the *Atlantic Monthly*, will facilitate an analysis of the defective gait of a patient affected with talipes calcaneus. It is evident that in such a patient some fragments are gone from the felloes of the human wheel. Practically the condition is not much better, so far as locomotion is concerned, than that of a person who has suffered amputation below the knee and is provided with a peg leg.

For the mitigation of this defect I have used in a number of instances a brace which fills, partly at least, the place of the paralyzed muscles, and restores to the patient the ability to walk as though he were able to rest his weight on the anterior part of the affected foot. It consists of an upright and a foot-piece, the joint between the two being so constructed that the foot-piece falls but cannot be raised beyond a right angle with the upright. The foot and leg of the patient are attached to the foot-piece and the upright respectively, and as these component parts of the brace cannot be flexed the one on the other past a right angle, it follows that in standing and walking the foot will remain at right angles with the leg.

Fig. 2.

Fig. 2 represents the steel frame of such a brace for the left foot. Buckles are attached at A, B, D, and E. A strap passes from A to B, across the front of the leg, and another, riveted at C, has two free ends, one of which is buckled at D and the other at E.

Fig. 3.

Fig. 3 represents the feet of a girl, seventeen years of age, who has talipes calcaneus of the left foot, the result of infantile paralysis. She is otherwise well-developed. Without the brace, which she has worn for six years, she is unable to rest any part of her weight on the anterior part of the left foot, a defect which is the result of paralysis of the muscles acting on the tendo Achillis. The extent of the paralysis in this case may be appreciated by observing the difference between the two calves. They measure 9½ inches and 12⅜ inches in circumference, a difference in favor of the unaffected limb of nearly three inches. The figure is copied from an instantaneous photograph, for which I am indebted to the kindness of my friend, Dr. Laurence Johnson, and shows the patient in the position of running. She is poised on tip-toe, an attitude which she cannot assume on the left foot without the help of the brace. The improvement effected by this simple apparatus is highly appreciated by the patient. Her walking is greatly improved by it, not only with regard to grace of motion, but also in her ability to endure prolonged walking without fatigue.

[1] Read before the New York Orthopædic Society, April 30, 1885.

[2] See an interesting historical note by Dr. O. P. Hubbard in The Medical Record, May 19, 1877, pp. 314, 315.

[3] The Human Wheel, its Spokes and Felloes. By Oliver Wendell Holmes. Atlantic Monthly, May, 1863, pp. 567, 580.

A consideration of the action of this brace shows that it transfers to the vicinity of the tubercle of the tibia the pressure and friction which ordinarily fall on the anterior part of the sole of the foot. As this bony process supports a large part of the weight of the body in the kneeling posture, it follows that a patient wearing this brace and standing in the position represented in Fig. 3, feels a compound sensation of standing and kneeling.

It is not to be supposed that this apparatus will restore the wasted muscles, but it will prevent the unseemly enlargement of the heel and extreme elevation of the anterior part of the tarsus, which are often found in patients affected with talipes calcaneus who have passed neglected through the years of development and growth. It may perhaps be added that the muscular fibres of the calf are in a better condition for development when protected by this apparatus, than when they are stretched to their limit by the overpowering weight of the body at every step. When applied in the case of an adult, the brace is a prothetic instrument, an artificial substitute for a natural part that is absent, an aid in locomotion, rather than a therapeutic agent. As such it is in use, and would be more widely used but for the expense attending its construction, repair, and renewal.

In the construction and application of this apparatus certain points should receive especial attention. In the first place, considerations of a sentimental nature should not prevent the use of mechanism strong enough to accomplish the purpose in view. Here, as in the case of the hip-splint, the weight of the body is to be supported in walking and running. The brace represented in the figures weighs a pound and a half. The sheet steel used for the foot-piece is nearly three-sixteenths of an inch thick. The curved piece is mortised and receives the top of the upright as a tenon. The stop-joint requires especial care in its construction, and should in use be frequently oiled. Each step of the patient inflicts a blow on a portion of this joint, which is worn away in a few weeks, so that the angle between the two parts of the brace is less than 90°, and the effectiveness of the apparatus is diminished. To save renewing this joint the round plate may be readjusted on the side of the foot-piece in such a way as to restore the right angle, or the same effect may be produced by a few blows of a hammer on the side of the upright near its anterior border, a short distance from the joint. The upright is made of soft steel, and its anterior edge at this point is given additional thickness with this proceeding in view.

In the application of braces for the correction of either talipes equinus or talipes calcaneus it is important to keep the axis of the leg and that of the upright portion of the brace in the same lateral plane, or at least parallel one with the other when viewed from the side. In the treatment of equinus the loss of this parallelism may allow the heel to come in contact with the foot-piece of the apparatus while the angle between the leg and the foot is unchanged. In the treatment of calcaneus it will be seen, by a reference to Figs. 2 and 3, that the maintenance of parallelism depends on the drawing short of the straps passing from A to B, and from C to E. Fortunately it is found in practice that the patient voluntarily keeps both of these straps buckled short, in order to secure improvement in walking. But the webbing which crosses the front of the leg below the knee is soon torn by the teeth of the buckles and gives way under the strain to which it is subjected. It is well, therefore, to attach it by two buckles, one on each side of the leg, so that it may be moved along and new points exposed to the wear and tear. A callus will form under this webbing, as the leg here receives the pressure and friction which ordinarily fall to the lot of the anterior part of the sole of the foot. It is well, therefore, to interpose several folds of blanketing between the webbing and the limb at this point.

Beyond this, the apparatus needs no lining or padding, excepting that the foot-piece may be lined first with adhesive plaster to protect the steel from rust, and then with a piece of russet leather fastened with two small copper rivets, and extending, for the sake of cleanliness, around the stop-joint. The curved piece at the top of the upright may be left without lining, as it scarcely touches the limb, its only function being to provide a point of attachment for a buckle on the inner side of the limb. The brace is worn over a stocking. With a second stocking drawn over the brace the appearance is nearly normal.

In case of valgous complications the ankle may be supported laterally by webbing on the inner side, appropriately fastened to the foot-piece and the upright, the outer border of the foot being duly protected from the pressure of the vertical part of the foot-piece.

Reports of Hospitals.

ST. LUKE'S HOSPITAL.

CANCER OF THE PERITONEUM.

REPORTED BY SAMUEL T. KING, M.D.,
EX-HOUSE-PHYSICIAN.

THE following report of three cases of carcinoma of the peritoneum is abbreviated from the records of the hospital. The absence of rise in temperature—except in one of the cases, which presented a slight elevation for a few days—and of tenderness, and the slight amount of pain, except that due to the great distention of the abdomen and tormina in one case, should be remarked.

CASE I. (Service of Dr. A. Brayton Ball.)—Annie D——, aged nineteen, single, a native of Ireland, and a domestic, was admitted to the hospital August 31, 1883. Her family history was good. Previous health had been very good. She first noticed a painless swelling of the abdomen six weeks prior to entrance, and this increased so rapidly that in two weeks she suffered from orthopnœa. With the intention of relieving this latter symptom, as well as the possible removal of the tumor, nineteen days before entrance patient underwent an operation, during which considerable ascitic fluid was removed and cancer of the peritoneum was made out. The cancerous mass was not removed. With the exception of a slight pain on the left side of the abdomen before this operation, she has suffered no pain whatsoever. On entrance she complains only of the enlargement of the abdomen. Physical examination reveals a hard, insensitive mass, filling up a large portion of the abdomen, not connected with the liver, spleen, or uterus; with a slight amount of ascites. While in the hospital she suffered from almost incessant vomiting, and rapid loss of flesh and strength. On entrance the temperature reached 103°, but it gradually fell to normal in the course of six days. The pulse ranged between 130 and 150. On September 30th it was noted that there was severe pain in the back. Patient died September 9th, ten days after entrance.

At the autopsy, twenty hours later, there was found in the abdominal cavity a hard mass which corresponded to the site of the omentum. There were several secondary deposits in the right pleura, capsule of liver, and other portions of the peritoneum. There were signs of old and recent peritonitis. Uterus was normal. The ovaries were nodular and bound by old adhesions to each side of the uterus.

CASE II. (Service of Dr. Geo. S. Wheelock.)—Annie M——, aged about fifty-seven, single, Irish, a child's nurse, was admitted to the hospital February 14, 1884. Her memory was very poor, and it was with the greatest difficulty that anything in regard to her past history could be learned. She had had intermittent fever in 1861. About three months before entrance she first noticed that her abdomen was swollen, and at the same time she began to vomit, and one month later œdema of the feet appeared. She does not remember to have had any pain. There had been no ocular symptoms or headaches. On

admission she complained of ascites and œdema of lower extremities, anorexia, pyrosis, and occasional vomiting. Patient is senile, and poorly nourished; there is no icterus. Temperature normal; pulse somewhat accelerated. The superficial abdominal veins are enlarged. She suffered some while in the hospital from general abdominal pains. Her condition continued apparently about the same, except, perhaps, some increasing weakness, until February 26, 1884, at 6.50 P.M., when she suddenly ceased breathing. No diagnosis had been made.

At the autopsy, twenty hours afterward, the peritoneal cavity was found to contain 284 ounces of clear serum. Both parietal and visceral peritoneum were everywhere studded with miliary masses, which in places were gathered together to form cauliflower growths of considerable extent. The heart was small, its tissue brownish and fatty. There was some chronic diffuse nephritis. The remaining organs were negative.

Microscopical examination by Dr. Frank Ferguson: All the miliary masses above alluded to are carcinomatous in structure. The fibrous stroma is quite scanty. The alveoli are large, and very generally the cells in the centres of the alveoli have undergone the granulo-fatty degeneration. The cells at the periphery of the epithelial masses within the alveoli are distinctly nucleated, of small size, cuboidal in shape.

All the masses examined presented the same appearance.

CASE III. (Service of Dr. Geo. S. Wheelock.)—Thomas B——, aged twenty-eight, married, an Englishman, a machinist, was admitted to the hospital July 16, 1884. He gave no family history of cancer, and he had never been sick. Three months before entrance he began to be very constipated, and to lose flesh and strength, and six weeks later his abdomen began to increase in size. Since then there has been varying distention of the abdomen, at times very great, and accompanied by tormina and pain, but at no time completely disappearing. There has been nothing characteristic in his stools; no enteralgia. Vomiting began three weeks before entrance, and his skin became slightly jaundiced. On admission patient is cachectic, markedly anæmic. Appetite is fair. The bowels are obstinately constipated. Physical examination reveals extreme distention of abdomen, which gives a tympanitic note on percussion, a small amount of ascites, some enlargement of the inguinal glands on both sides. There was no enlargement of liver or spleen, no stenosis of the rectum. No tenderness on pressure over the abdomen. Respiration and temperature were normal. Some acceleration of the pulse. Patient continued to suffer from almost persistent vomiting, and was nourished largely by nutritive enemata. August 5, 1884, after gradually losing flesh and strength, he died at 6 A.M., not having apparently suffered any pain, except what could be explained by the tormina and the extreme distention of the abdomen.

At the autopsy, nine hours afterward, there were found nodular masses throughout the peritoneum, both visceral and parietal, also a constriction of the colon about thirty inches from the anus, which barely admitted a sound three-fourths of an inch in diameter. No pathological change of any importance was found in any of the organs.

On incising the abdomen the immensely distended and enlarged colon escaped from the abdominal cavity. All the small masses are cancerous nodules, and the enormously distended colon above the stricture was filled with fluid fæces. The latter fact explains the reason for several unsuccessful attempts to relieve the extreme distention during life by punctures with a hypodermic needle, although there was sufficient gas mixed with the fæces to give a decided tympanitic percussion note.

MELANOSIS.—M. Bard says that melanosis is a parasitical disease, and that the pigmentary matter is made up entirely of spores.

Clinical Department.

EXCISION OF A RIB FOR EMPYEMA.

DR. LEONARD C. MCPHAIL, of Brooklyn, relates the case of a child, eight years of age, suffering from empyema, following pneumonia and pleurisy. An incision was made in the eighth intercostal space, and thirty-two ounces of pus withdrawn. A drainage-tube was introduced, and the child did well for some weeks, until the ribs came together, expelling the tube, and pus reaccumulated in the chest. It was then decided to excise a portion of the eighth rib. This was done through an L-shaped incision in the integument, and after denuding the bone of its periosteum, a piece one and one-fourth inch in length was removed. The child suffered greatly from shock, but began to improve after a few days, and is now gaining rapidly. The wound is permanently closed, and the patient is in better health than ever before.

STONE IN THE BLADDER REMOVED BY THE SUPRA-PUBIC OPERATION.

DR. LEONARD C. MCPHAIL, of Brooklyn, sends us the history of a boy, eleven years of age, who presented the symptoms of vesical calculus. The diagnosis having been confirmed by examination with the sound, the high operation for removal of the stone was determined upon. This was performed by the writer, assisted by Dr. L. S. Pilcher. The patient having been anæsthetized, and the stone having been again felt with the sound, a catheter was introduced and about eight ounces of a warm boric acid solution (15 grs. to ℥j.) injected. A rubber bag was then introduced into the rectum, just above the sphincter, and was dilated with warm water. An incision, three and one-fourth inches in length, was made in the median line, and, the pyramidal muscles being held aside, the bladder was brought into view. The viscus was then incised from above downward, for a distance of one and a half inch, by means of a sharp-pointed bistoury, and the index-finger being introduced, the stone was felt lying loose in the bladder. This was removed by the forceps, and the bladder and wound were washed with a boric acid solution. Drainage from the bladder was provided for by two parallel rubber catheters wired together, and passed down to the fundus. The edges of the wound were approximated by two deep and two superficial sutures, and a dressing of iodoform and borated cotton was applied. The case progressed favorably, with occasional rise of temperature and some suppuration of the wound, and on the twelfth day after the operation the urine began to pass through the urethra. On the seventeenth day the wound in the bladder was closed and the temperature was normal. The stone weighed seven drachms, and measured four inches in its greater circumference by three and three-eighth inches in its lesser; it was a trifle over one and a half inch long by one and one-fourth wide.

OPACITY OF THE CORNEA PRODUCED BY COCAINE.

DR. W. FLETCHER WILSON, of Denver, Col., writes that he has used cocaine in fifty-six operations upon the eye, with almost uniform success. In one case an enucleation was performed with but little pain, but in another operation of the same kind he was obliged to resort to ether. In two instances the cocaine gave rise to a peculiar symptom. The first case was that of a man, forty-seven years of age, who had lost his left eye some years before from an injury. The right eye had suffered from ulceration of the cornea, with perforation and adhesion of the iris. A large opacity covered the centre and inner portion of the cornea. A four per cent. solution of co-

caine was used, and iridectomy was performed on the outer side. Cocaine was then employed instead of atropine three times a day. On the following morning the clear portion of the cornea began to assume a hazy and pitted appearance, and this continued to increase up to the third day, when the cornea was of a light yellow color and with a roughened surface. The cocaine was then discontinued and a one per cent. solution of atropine substituted. Immediate improvement followed, and continued up to the fourth day, when the cornea was smooth and the cloudiness had disappeared. In a case of discission of soft cataract, in a child, ten months of age, cocaine was used during the operation, and twice a day afterward. The case seemed to be doing well up to the third day after the operation, when the cornea began to present the same hazy and pitted appearance as in the first case. As the condition continued to grow worse, a solution of atropine (2 grs. to ℥j.) was substituted for the cocaine. Under this treatment the corneal cloudiness soon disappeared. That this symptom was due to the cocaine would seem to be shown by the similarity of the two cases and by the rapid and immediate improvement following the discontinuance of the drug in each instance.

THE COMMUNICABILITY OF SCARLET FEVER THROUGH A THIRD HEALTHY PERSON.

Dr. D. R. Waggoner, of Oxford, Neb., relates the following instances in which the virus of scarlatina was evidently conveyed from the sick to the well by a third healthy person. Mrs. R—— had been visiting a sister, five of whose children had scarlet fever. She returned twenty miles to her own home and within five days her own little girl was attacked with the disease. There had been no scarlatina in the neighborhood for months. A niece of Mrs. R—— spent several hours with her on the day following her return. This child was also seized with the fever on the same day as Mrs. R——'s daughter, and died of it the fourth day. Dr. Waggoner attended both these cases, and Mrs. R——'s niece died in his arms. On returning home after the child's death, his little boy, as was his custom, climbed into his lap and sat on his knee for perhaps an hour. Four days later this boy was taken with scarlet fever, and his older brother four days after that. As these were the only cases in the neighborhood it seems impossible to explain their origin except by the conveyance of the poison by a third person. Dr. Waggoner says that since this sad experience he has always worn rubber clothing in the sick-room of a scarlet fever patient. He also relates another instance, unconnected with these cases, in which the poison was conveyed in a similar manner.

Dr. A. H. Hewetson, of St. Clairsville, O., writes that in 1873 he attended a case of scarlet fever of very severe type. The case was an imported one, the first in that locality for more than a year. While making an application to the throat, Dr. Hewetson held the little patient on his knee, and upon his return home his own son climbed up into his lap before he had had time to remove the overcoat worn in the sick-room. Soon afterward this child was attacked with the disease, and subsequently the other children of the family suffered in like manner.

GLIOMA OF THE BRAIN.

Dr. N. Dodge, of Milwaukee, sends a report of the following interesting case. In January, 1883, he was consulted by Mr. H——, a clergyman, who stated that three years previously, after an unusual mental effort, he was suddenly seized with an epileptic attack of great severity. Since that time he had had several convulsions of mild type and occurring at long intervals. He had taken large quantities of bromide of potassium and had made a voyage to the Azores, but without obtaining any relief. At the time of the consultation he had not had a fit for several months, but suffered from a tremor of the left hand which was increased by attempts at voluntary motion and by mental excitement. There was no paralysis, the various reflexes were normal, vision was unimpaired, and the optic nerve presented a healthy appearance. Headache of a deep-seated character, not constant, was a prominent feature in the case. At times there were ringings in the ears, and a feeling of impending danger. The patient had a peculiar, excited manner, but he reasoned well on ordinary topics and showed slight, if any, mental impairment. There was a history of nervous disorders in his family. Dr. Dodge diagnosed disease, probably tumor, of the right side of the brain near the base, and advised absolute rest and put the patient on general tonic treatment. The absence of mental symptoms and of disturbance in articulation, and the subsidence of the convulsive attacks, seemed to exclude sclerosis. The patient was not seen again until the following spring, at which time he presented a marked aggravation of all the previous symptoms. The tremor now involved the entire left side, was rhythmical in character, and absent only during sleep. The patient was now also much changed in manner and disposition, and could with difficulty continue a conversation on one subject for any length of time. From this time he continued to grow rapidly worse, until September, when he was taken with what appeared to be acute meningitis. During this attack, which lasted about two weeks, he became hemiplegic on the left side. He subsequently partially recovered from this attack so as to be able to walk with the assistance of a cane, dragging the left leg. The patient remained in this condition for several weeks, when he was suddenly seized with violent headache, symptoms of compression came on, and he died comatose in a few hours.

The post-mortem examination revealed a large gliomatous tumor of the brain, occupying nearly the entire under-surface of the middle lobe on the right side, sending prolongations to the frontal lobe and also encroaching upon the pons and right crus cerebri. The right optic tract was also flattened by the pressure of the tumor, which invaded the brain substance to such an extent as to form the floor of the posterior cornu of the right lateral ventricle. The corpus striatum and optic thalamus were not involved in the morbid process. The hemiplegia was probably produced by pressure of the right crus cerebri. The interesting features of this case were the early and persistent tremor limited to the left side, and the absence of paralysis until late in the course of the disease.

PEROXIDE OF HYDROGEN IN AURAL THERAPEUTICS.

Dr. Frank Allport, of Minneapolis, Minn., writes that he has found the peroxide of hydrogen very serviceable in cleansing the middle ear preparatory to an insufflation of boric acid, iodoform, and other antiseptic powders. This substance, H_2O_2, is a combination of so unstable a character that it readily decomposes, liberating one atom of hydrogen upon contact with various substances, pus among the number. The oxygen thus liberated is in a nascent condition and very active, and will force pus to escape in the form of bubbles from any cavity in which it may be confined. Dr. Allport first employed peroxide of hydrogen to cleanse the exposed mastoid cells after an operation, and was so pleased with its action in this case that he commenced using it in chronic suppuration of the middle ear. His method of employing the agent is very simple. The meatus is first wiped out with cotton, and then a small quantity of the peroxide is instilled and allowed to remain for a minute or two, during which time the pus will escape bubbling from the meatus. The canal is now cleansed again and a further instillation of the peroxide is made. The process is repeated until no

effervescence is noticed, which is usually after the second application. The parts are then thoroughly dried and the insufflation is made. When the opening in the membrana tympani is so small as to render it difficult for the fluid to enter, a middle-ear syringe is used, and two or three drops passed into the tympanum. Dr. Allport states that the success attending this mode of treatment in his hands has been very gratifying. In order to obtain the best results the peroxide of hydrogen must be fresh. After standing a few weeks it loses much of its strength, and it should be kept in a colored bottle, away from the light and in a cool place.

A FAILURE WITH CHLOROFORM IN THE TREATMENT OF TAPE-WORM.

Dr. J. J. Smith, of Boston, Mass., relates the case of a man, forty-two years of age, who came to him with the complaint that he frequently passed worms from the bowel while at work. He said that he had passed some while on his way to the doctor's office, and on examining the clothing several segments of tape-worm were found. The patient was instructed to fast for twenty-four hours, and at the expiration of that time received a mixture containing chloroform ℥ j ; croton-oil, gtt. ss ; mucilage of acacia and castor-oil, āā ℥ jss. Four hours later he took two ounces more of castor-oil. In two hours he had a copious evacuation, passing, however, but two or three segments of the worm, the longest of which was less than two inches. In two weeks the chloroform was repeated after another fast of twenty-four hours, with the result of causing the expulsion of a segment about twenty inches in length. The patient is now again passing several pieces of the worm each day in the same manner as before the treatment was begun.

BUCKWHEAT FLOUR IN DIABETES.

Dr. A. M. Duncan, of Hamler, O., writes that Dr. Alvord, a retired practitioner of that place, who is a sufferer from glycosuria, finds more relief from a diet of pure buckwheat-flour cakes than from anything else. While he adheres to this food the urine becomes nearly normal in quantity and quality, there is no gastric distress, and the pain in the eyes—nearly destroyed by chronic iritis—is markedly relieved. On resuming the use of wheat bread and other starchy foods, the symptoms become aggravated, to be again relieved upon a return to buckwheat.

PARALYSIS FROM THE USE OF COCAINE (?).

A correspondent, E. F. H., sends us an account, in substance as follows, of a disagreeable experience of which he was himself the subject. On December 13th, he writes, he went to a dentist for the purpose of having a carious tooth filled. On account of the excessive pain attending the process of excavation, cocaine in four per cent. solution was used very freely. On the morning of the second day following the operation, December 15th, he found that, on attempting to swallow, a portion of the fluid escaped from the right side of the mouth by reason of inability to close the lips firmly. "This condition undoubtedly began its development much earlier than the time of its discovery, as it went on in its course of extension for the two succeeding days, involving every function of the entire right side of the head, rendering me deaf and unable to close the eye. The brain was depressed as to destroy all continuity of thought, and I was unable to read or to exercise any mental function whatever. I should have expected the same class of cerebral symptoms from an over-dose of opium." This paralyzed condition remained stationary for ten days, and then began slowly to improve, until, at the expiration of six weeks, it had nearly disappeared, "leaving only a sensitiveness to cold, and a leathery, subdued feeling, which exists even to the present time." The writer says that he attributes his sufferings in this instance to cocaine only because he can find no other explanation, for his habits are regular, and his general physical condition as nearly perfect as it is possible to be. But in view of the fact that more than twenty-four hours intervened between the use of the cocaine and the appearance of the first symptoms, it seems more than probable that the drug had no hand in their production.

REDUCTION OF THE FUNIS.

Dr. Daniel E. McSweeny sends us a description of the method employed by him with success in eight cases of replacing a prolapsed funis. It consists simply in passing the index-finger through the most dependent loop of the cord, and then slowly and gently twisting the funis upon itself. In this way the presenting object is soon formed into a ball which can be readily grasped as a whole and replaced above the brim of the pelvis. When once inside the uterus, its natural elasticity causes it to unwind, thus obviating all danger of strangulation. In the meanwhile, the hand is retained in the vagina until the head of the child engages. Dr. McSweeny relates a case in which this complication occurred, and in which he employed this method of reduction with perfect success.

COCAINE OR APPREHENSION?

Dr. M. A. Veeder, of Lyons, N. Y., writes: "In employing cocaine in operations about the eye, it should always be remembered that the anæsthesia produced by it is purely local. The patient is fully conscious of what is being done, though free from pain. Now, there are persons who faint during so painless an operation as vaccination, and it is not strange that there are those who feel sick and faint when they see an instrument coming directly toward the eye. The sensations thus experienced are to be ascribed to the nervous condition of the patient rather than to any poisonous effect of the drug, as some have assumed.

The Massachusetts General Hospital.—"The Seventy-first Annual Report of the Massachusetts General Hospital and McLean Asylum" presents a concise statement of the work of the year 1884, and is replete with interesting information and tables of valuable statistics. Its large endowment and numerous subsidiary funds make us realize that our rich men are, as a class, behind those of Boston in liberality toward medical institutions. We note with interest the fact that a separate establishment for convalescent patients is a feature of the management of the institution. Gratifying results have followed this division of the work. This topic should command the attention of hospital managers everywhere. The ambulance service of Boston seems, from the brief allusion made to it in this report, to be in its infancy, and far behind that of New York.
